NUMBER 1

HURTHLE CELL TUMOR OF THE THYROID GLAND

ABRAHAM O. WILENSKY, M D, F A C S, and PAUL A. KAUFMAN, M D, New York, New York

THE established value of clinicopathological studies has prompted us to report 2 cases of an unusual thyroid tumor which, because of its relative rarity and undetermined clinical significance, should be added to the meager relevant literature so that one may arrive at certain conclusions from the examination of the collective experience.

The following questions will be discussed: (1) The cell of origin of the Hurthle cell tumor; (2) the important clinical phenomena associated with this tumor; (3) the relationship of the tumor as regards its benignity or malignancy; (4) the treatment; and (5) the value of radiation therapy.

GROSS AND MICROSCOPIC ANATOMY

The question of cell classification of the Hurthle cell type of neoplasm with special regard to the cell prototype has not yet been definitely established. The most likely sites of origin are the cells of the thyroid or of the branchiogenetic structures, especially the parathyroids¹

The thyroid It has always been difficult to differentiate the normal elements of the thyroid because of the extreme lability of its cellular elements. Variations in size and structure occur from day to day, and according to the season, the climate, the geographi-

cal location, age, sex, food, the state of nutrition, and, most important of all, in accordance with the amount of available iodine.

In mammals the thyroid consists of two lobes which lie on either side of the trachea, about the level of its juncture with the larynx. There is marked variation in its position, both in different, and within the same, species. The human thyroid in particular varies greatly from the theoretically normal type. Complete absence of the thyroid anlage has been observed (Maresch, 1898; Erdheim, 1904). A third "pyramidal" lobe occurs commonly. Isolated masses of thyroid tissue are found along the line of descent of the thyroglossal tract usually known as "lingual," "sublingual," "suprahyoid" and "infrahyoid" thyroids. Accessory or aberrant thyroid tissue apart from that developed from the thyroglossal tract occurs commonly in man in the region of the ascending and transverse portions of the aortic arch. More rarely thyroid fragments are present in the thymus, at the bifurcation of the trachea, or as far down as the esophageal opening in the diaphragm.

There is some doubt as to the single and median origin of the thyroid in mammals. In all other vertebrates the uniformity of the origin of this gland has long been established by the work of Stieda (1881), Born (1883), His (1885), Kastschenke (1887), Van Bemmelen (1889), Maurer (1888, 1889), and Herrmann and Verdun (1900). The thyroid gland is developed from a median diverticulum on the summit of the tuberculum impar which grows downward and backward as a tubular duct, which subsequently divides into a series of cellular cords, from which the isthmus and lateral lobes of the thyroid gland are developed. The ultimo-branchial bodies from the fifth pharyngeal pouches are enveloped by the lateral lobes of the thyroid gland

¹We are indebted to Keibel and Mall's Embryology, to Cowdry's book on Special Cytology, and to Gray's Anatomy for the embryological, anatomical and microscopic data which follow.

and atrophy and do not form true thyroid tissue. The thyroglossal duct which connects the diverticulum with the pharynx undergoes degeneration and disappears later, its upper end being represented by the foramen cecum of the tongue and its lower by the pyramidal lobe of the thyroid gland.

The development of the thyroid anlage usually occurs as anastomosing solid cords which are cut up by the ingrowth of vessels and stroma to form a follicular structure. The primary follicles arise by the rearrangement of the cells, cell proliferation, increases in the size of the cells and lumen formation. The further growth of the thyroid requires the formation of new follicles from the primary follicles. These are usually formed from solid epithelial bands or hollow buds the cavities of which are at first continuous with the original follicle lumen.

The unit of the thyroid is the individual follicle. The follicles are irregularly rounded or elongated closed spaces of variable dimensions lined by a single layer of cuboidal epithelium resting on a condensed layer of connective tissue which, however, is not considered a true basement membrane. Langendorff and all subsequent observers have demonstrated two types of cells: (1) a majority of chief cells and (2) a minority of colloid cells. There is a variable distribution of the colloid cells and occasionally whole follicles may be composed of these cells. The evidence which is at present available would indicate that the chief cell (the Bensley (filled colloid) cell and the Langendorff (empty colloid) cell) probably represent stages of the secretory cycle through which the characteristic thyroid cell passes.

There are variable groups of small follicles and undifferentiated thyroid cells lying between the larger follicles. Most numerous during fetal life and infancy they normally decrease or disappear with age. They may be considered as new follicles in various stages of development as a result of increased growth stimulation whenever a sufficient stimulus for increased thyroid activity is applied which usually happens in association with goiter formation.

Actively phagocytic reticulo endothelial cells (tissue mast cells of the older workers) occur also in the interfollicular stroma. According to Williamson and Pearse (1926) they are more prominent in the hyperplastic gland and these authors assume that they take part in the normal activities of the thyroid. These cells have no morphological relationship to the Hurthle type cell.

Large oxyphilic cells are also described by Hurthle, Baber, Langendorff and others as occurring in the interfollicular spaces of the normal thyroid. There is no uniformity of opinion concerning these cells however.

The parathyroids. The parathyroid bodies are developed as outgrowths from the third and fourth branchial pouches. In connection with the fourth parathyroids a cystic endodermal rest corresponding to the postbranchial or ultimobranchial body or

lateral thyroid anlage may usually be found. Normally there are four glands situated two on either side, very difficult to recognize and find, there is very little variation from this normal.

Microscopically the parathyroids consist of intercommunicating columns of cells supported by connective tissue containing a rich supply of blood capillaries.

The parenchyma of the parathyroid is made up of closely packed relatively large cells. Three types of cells are distinguishable: (1) chief cells, (2) small dark chief cells (Peterson 1903, Getzowa 1907, Noodt, 1922) and (3) large bright oxyphilic cells (Welsh, 1898).

The clear chief cells appear to be the essential type. They have clear almost unstaining plant like non granular protoplasm with relatively large pale vesicular eccentric nuclei.

The dark chief cells are at best only a subgroup of the chief cells and in appearance they are intermediate between the clear chief cells and the oxyphil cells. There seem to be suggestions that they represent the early stages of the large oxyphil cells.

The oxyphil cells appear in late childhood and are much larger than the chief cells, occur singly or in groups and are characterized by large amounts of granular protoplasm which stain intensely with acid dyes. The nucleus is much smaller than in the chief cells and the chromatin filaments are closely packed and deeply staining.

In infancy only clear chief cells or dark chief cells are present. Oxyphil cells are present only in certain species of animals and in man they increase from about the tenth year of life onward. Three types of cells represent different stages of secretory activity, the oxyphil cells being the mature cells.

HISTORICAL REVIEW

With this anatomical background of the various cell types and structures to be considered in determining the origin of the so called Hurthle cell tumor, we review the reported cases in order to reveal their common features.

As was indicated previously Hurthle in 1894 described a large oxyphilic parafollicular thyroid cell as a part of the structure of the normal thyroid gland. He did not describe any thyroid tumors composed of this cell type but the similarity between the cell he described and that forming the prototype of the tumors we are discussing prompted later writers to designate them by the term "Hurthle cell tumors."

The first reference to these tumors was made by Langhans in 1907, who applied the descriptive designation "small alveolar, large cell struma" to them. He reported 5 such cases, the histories of which are abstracted here:

CASE 1 From Professor Kocher. Female, aged 55 years, had a colloid struma of the isthmus which had been growing rapidly in the last 3 months. Two nodules were noted, one walnut sized, one 9 by 5½ by 4½ centimeters, each with smooth surfaces. On section, there was noted a lobular structure of gray, brown, red color, translucent, very granular, and with radiating septa containing transected vessels. There was evidence of recent hemorrhage in both nodules.

CASE 2 From Professor Niehaus. Male, aged 68 years, had had a goiter for 15 years. Respiratory difficulty had been noted for 1 year, and had become worse in the last 3 weeks with rapid growth of tumor. Exitus occurred immediately after operation. The postmortem examination showed metastases to the lungs and the liver.

CASE 3. From the Surgical Clinic of Bern. Female, aged 41 years, had had a thyroidectomy 12 years ago, for a large growth. Recurrence had taken place, with rapid growth in the preceding 6 months. Tumor measured 12 by 8.5 by 10 centimeters and was adherent to the trachea. The patient died and the postmortem examination showed pulmonary metastases.

CASE 4 From Professor Kocher. Female, aged 40 years, had a rapidly growing tumor. No further clinical details were given.

CASE 5 From Professor Kocher. Male, aged 32 years. Two surgical specimens were obtained, one egg-sized, one 6 centimeters in diameter. No clinical details were given.

Lobenhoffer, in 1909, while discussing thyroid secretion, refers to 2 cases, abstracted below, which also fit into the category we are describing.

CASE 6 Female, aged 12 years, had a goiter which had grown rapidly in the preceding 6 months. Marked pressure symptoms were present. A resection of the left lobe and isthmus was performed. A small alveolar large cell struma of Langhans was demonstrated microscopically, all gradations being seen between small finely granular acidophilic cells and large coarsely granular cells. The case was considered benign.

CASE 7 A 40 year old woman was operated upon for goiter. No clinical data were submitted. The specimen presented the typical microscopic picture, and was considered benign.

Wegelin, in his monograph on the thyroid in Henke and Lubarsh's *Handbuch*, states

FIG. 1. Diagrammatic representation of the development of the thyroid, parathyroid, and thymus glands. *Tc*, the tonsil; *Pl*, the parathyroids, *I*, *II*, *III*, and *IV*. *Thy*, the thymus, *I*, *II*, *III*, and *IV*. *Ub*, the ultimobranchial body, *1*, *2*, *3*, and *4*, the branchial pouches. (From E. V. Cowdry, *Special Cytology*, after O. Grosser in Keibel and Mall, *Human Embryology*, 1912, 2: 461.)

that he has seen several such tumors in all age groups but that they were all benign. He submits no further clinical data.

Ewing, in his book on neoplastic diseases, also makes passing reference to what he calls "struma postbranchialis (Getzowa) or small alveolar large cell adenocarcinoma (Langhans)" stating that he has examined two tumors answering to that description, but he likewise submits no clinical data and does not indicate whether they were benign or malignant.

Haagensen describes 2 cases of thyroid carcinoma of the "small alveolar, large cell (Hurthle cell)" type. These reports, which are fairly complete, are as follows:

CASE 8 Female, aged 37 years. In 1918 patient had an enlargement of the thyroid associated with nervousness and menorrhagia. In 1924 a partial thyroidectomy was performed. The tumor measured 8 by 5 centimeters and there was perforation of the capsule. "Patient referred to Memorial Hospital with considerable tumor remaining." Three half erythema doses of x-ray (low voltage) were given between October, 1924, and January, 1925. The tumor slowly decreased in size. In October, 1930, the tumor was about the same. Pathology: thyroid small alveolar, large-cell (Hurthle cell) carcinoma, Grade II.

CASE 9 Female, aged 38 years. In 1906 following childbirth a goiter was noted which increased in size slowly. In December 1915 the tumor was removed. The specimen was 11 by 8 by 5 centimeters was encapsulated, and it was thought to have been completely removed. In 1914 there was a small recurrence which was treated with radon implantation in July, 1925. In January, 1926 cough and hemoptysis occurred and the patient was admitted to the Memorial Hospital. An 8 by 6 centimeter hard, irregular mass was present at the base of the neck with pulmonary metastases and widening of the superior mediastinum. Improvement occurred for 2 months following high voltage x ray therapy. The cough and hemoptysis ceased after 1 month and the pulmonary metastases decreased in size.

In 1927-1928 4 additional x ray treatments were given. The condition remained unchanged. In July 1929 the cough reappeared and the thyroid mass increased in size in spite of continued x ray therapy. In October 1929, there was back pain. x ray examination showed metastases in the spine. additional x ray therapy was given and a brace was applied. In 1930 x ray therapy was continued. In 1931 the patient weakened considerably; the cough persisted. The neck and pulmonary recurrence remained unchanged but the vertebral metastases increased. Pathology: thyroid small alveolar large cell (Hurthle cell) carcinoma, Grade II. Large cuboidal cells with an acidophil cytoplasm and with small nuclei form compact small irregular alveoli.

Eisenberg and Wallerstein report a single case of Hurthle cell adenoma which was unusual in that it was associated with a toxic goiter.

CASE 10 A woman aged 54 years had a swelling of the neck for years. It had grown appreciably larger in the preceding 5 months during which time she had three spells of unconsciousness each lasting 1 hour. The spells were accompanied by diffuse muscular twitching. Only slow loss of weight occurred in the preceding 5 months with cardiac palpitation on exertion and excitement. No nervousness or perspiration were noted. Menses were normal. The thyroid examination showed diffuse enlargement of both lobes of the thyroid. The neck veins were distended. There were no eye signs and no tremors. The heart was slightly enlarged with a systolic murmur at the apex. A basal metabolic rate of +40 fell to +18 after Lugolization. A right subtotal hemithyroidectomy was done. Ten months later the patient was readmitted with swelling of the left lobe and isthmus of the thyroid. The basal metabolic rate was +41. A left hemithyroidectomy was performed. The basal metabolic rate then fell to +3 and 4 months later to -18.

The microscopic picture showed many small alveoli long strands of palisade like cells and occa-

sionally syncytium like masses. Some alveoli contained a small amount of colloid. The cells were large fat free either polyhedral or irregularly shaped. They were clearly outlined. The cytoplasm was oxyphilic and finely granular. The nuclei were eccentrically placed small and vesicular with nucleoli and they were rich in chromatin. No mitotic figures were seen though a few double nuclei were noted. In addition the picture of toxic non exophthalmic goiter was present with many areas of lymphocytic infiltrations. The diagnosis was toxic non exophthalmic goiter and Hurthle cell adenoma of the thyroid gland.

Clute and Warren, in a review of 226 cases of thyroid cancer, found 1 case of adenocarcinoma of the Hurthle cell type but they did not report any clinical data other than an excellent photomicrograph exhibiting the characteristic appearance of the tumor. They remark "While admittedly the cells resemble the oxyphil cells of the parathyroid, they appear to us to resemble even more closely the acidophilic phase occasionally encountered in the thyroid epithelium itself."

Our experience¹ comprises the following two cases.

CASE 11 Bronx Hospital No 38653. A house wife 47 years of age was admitted to the hospital with a history of generalized arthralgias for the preceding 4 1/2 years and a recent history extending over a period of 6 months of cardiac palpitation tremor sweating and loss of 40 pounds in weight. The physical examination revealed hypertrophic enlargement and restricted motion of all of the joints. There was a firm nodular enlargement of the right lobe of the thyroid gland. The blood Wassermann test was negative. The routine urine examination was also negative. The white blood count and differential count were normal. The vaginal and urethral spreads revealed no Gram negative diplococci. The basal metabolic rate was + per cent.

Following a brief period of Lugolization operation was performed. The tumor was found to involve the right lobe of the thyroid gland and was enucleated with such difficulty that a partial excision of the right lobe of the thyroid gland was necessitated together with the tumor.

The specimen was a reddish brown mass of tissue 3 by 2 centimeters in diameter with some evidence of a thin fibrous capsule about the tumor. Microscopic examination revealed adenomatoid areas in a lymphocytic stroma. There were small areas of adenoma malignum or early thyroid carcinoma. The outstanding feature however was the presence of

¹The pathological examination and the report to the microscopic picture in both of our cases was made by Joseph F. Henrich, Laboratory of the Bronx Hospital. We are indebted to him for his co-operation.

strands and alveoli with papillary overgrowth of Hurthle type oxyphilic cells of characteristic structure. The immediate postoperative course was uneventful and was followed by intensive radiotherapy with a radium collar.

Examination of the patient 3 years later revealed no recurrence of the tumor.

CASE 12 Bronx Hospital No 66465. A housewife, 47 years of age, was admitted with a 2 year history of a slowly increasing swelling in the neck. This was accompanied by some increased nervousness and sweating but there were no cardiac palpitation, tremor, exophthalmos, loss of weight, or any other symptoms of hyperthyroidism; no pressure symptoms were manifested. The physical examination revealed a diffuse firm enlargement of the thyroid gland, particularly on the left side, where a bruit was heard. There was slight cardiac enlargement but no other signs of cardiac disturbance. The white blood count was 8100, the polymorphonuclears, 80 per cent, lymphocytes, 18 per cent, and monocytes, 2 per cent. The routine urine examination was negative. The basal metabolic rate was +22 per cent. The uterus was moderately enlarged by the presence of a fibroid tumor.

Following a brief period of lugolization operation was performed and a large ovoid tumor of the left lobe of the thyroid was enucleated. The remainder of the left lobe of the thyroid was subtotally resected.

The tumor was 5 by 4 centimeters in diameter, brown, and fleshy in appearance. Microscopic examination revealed an area of compact cellular tissue characterized by cords and light foamy polyhedral acidophilic cells with small eccentric nuclei. The remainder of the thyroid gland exhibited areas of varying cellularity, colloid distention, and focal lymphoid infiltration.

The postoperative course was uneventful, and the patient has remained well to this date (8 months).

CLINICAL FACTS

A number of clinical facts have been extracted from this review of the available clinical records of the Hurthle cell type of tumor.

1. In only one of the recorded cases has there been any associated thyrotoxic phenomena. This was Eisenberg and Wallerstein's case. This is remarkable.

2. No case, except one of ours, has shown any association with joint or bone manifestations. In this case, the laboratory and clinical observations have shown no data which could either (a) associate the tumor with any parathyroid structure, or (b) give any inkling of

any metabolic disturbance usually associated with parathyroid activity.

3. There is no evidence that the presence of the Hurthle cell type of tumor has been associated with any other ductless gland disturbances.

4. In the recorded cases 4 "benign" and 6 "malignant" forms of Hurthle cell tumor are described, no statement as to the malignancy or benignancy being made in the remaining cases.

5. In at least 1 case (one of ours) several types of tumor seem to be present.

CELL OF ORIGIN OF HURTHLE CELL TUMOR

As is seen from the preceding anatomical and microscopic descriptions many cells differing only very slightly morphologically exist from which the Hurthle tumor might originate. Difficulty is added by the confusing terminology and nomenclature; for instance, Hurthle cell tumor, Langhans wuchernde struma, Getzowa struma, etc., may or may not be the same entities.

In Langhans' original description of these tumors the cells making up the parenchyma are described as large polyhedral oxyphilic granular cells about 15 or 30 microns in diameter arranged in small alveoli or trabeculae. The nuclei are eccentrically placed, about 6 to 8 microns in diameter, and contain a large amount of chromatin in clumps and threads with a prominent nucleolus. Langhans, as well as other observers, aptly noticed the resemblance of these cells to the parenchymatous cells of the liver and adrenal cortex. Of greatest possible significance, however, was the very close resemblance of the tumor cells to the oxyphilic cells of the parathyroid, a fact which lead a group of observers, notably Eisenberg and Wallerstein, to believe that the tumors are of parathyroid origin. The latter observers bolster up their anatomical data with clinical observations concerning the physiological effects of the tumor which they observed in their patient (*vide supra*).

Eisenberg and Wallerstein consider this as evidence of the presence of a functioning parathyroid tumor although data on the blood calcium or calcium metabolism are not

CASE 9 Female aged 58 years. In 1906 following childbirth a goiter was noted which increased in size slowly. In December, 1915 the tumor was removed. The specimen was 11 by 8 by 5 centimeters was encapsulated and it was thought to have been completely removed. In 1924 there was a small recurrence which was treated with radon implantation in July, 1925. In January 1926, cough and hemoptysis occurred, and the patient was admitted to the Memorial Hospital. An 8 by 6 centimeter hard irregular mass was present at the base of the neck with *pulmonary metastases and widening of the superior mediastinum*. Improvement occurred for 2 months following high voltage x ray therapy. The cough and hemoptysis ceased after 1 month, and the pulmonary metastases decreased in size.

In 1927-1928 4 additional x ray treatments were given. The condition remained unchanged. In July 1929 the cough reappeared and the thyroid mass increased in size in spite of continued x ray therapy. In October, 1929 there was back pain. x ray examination showed metastases in the spine. additional x ray therapy was given and a brace was applied. In 1930 x ray therapy was continued. In 1931 the patient weakened considerably, the cough persisted. The neck and pulmonary recurrence remained unchanged but the vertebral metastases increased. Pathology thyroid small alveolar large cell (Hurtle cell) carcinoma Grade II. Large cuboidal cells with an acidophil cytoplasm and with small nuclei form compact, small irregular alveoli.

Eisenberg and Wallerstein report a single case of Hurtle cell adenoma which was unusual in that it was associated with a toxic goiter.

CASE 10 A woman aged 54 years, had a swelling of the neck for years. It had grown appreciably larger in the preceding 5 months during which time she had three spells of unconsciousness each lasting 1 hour. The spells were accompanied by diffuse muscular twitching. Only slow loss of weight occurred in the preceding 5 months with cardiac palpitation on exertion and excitement. No nervousness or perspiration were noted. Menses were normal. The thyroid examination showed diffuse enlargement of both lobes of the thyroid. The neck veins were distended. There were no eye signs and no tremors. The heart was slightly enlarged with a systolic murmur at the apex. A basal metabolic rate of +40 fell to +18 after lugolization. A right subtotal hemithyroidectomy was done. Ten months later the patient was readmitted with swelling of the left lobe and isthmus of the thyroid. The basal metabolic rate was +41. A left hemithyroidectomy was performed. The basal metabolic rate then fell to +3 and 4 months later to -18.

The microscopic picture showed many small alveoli, long strands of palisade like cells and occa-

sionally syncytium like masses. Some alveoli contained a small amount of colloid. The cells were large, fat free either polyhedral or irregularly shaped. They were clearly outlined. The cytoplasm was oxyphilic and finely granular. The nuclei were eccentrically placed small and vesicular, with nucleoli, and they were rich in chromatin. No mitotic figures were seen though a few double nuclei were noted. In addition the picture of toxic non exophthalmic goiter was present with many areas of lymphocytic infiltrations. The diagnosis was "toxic non exophthalmic goiter and Hurtle cell adenoma of the thyroid gland."

Clute and Warren, in a review of 226 cases of thyroid cancer, found 1 case of adenocarcinoma of the Hurtle cell type, but they did not report any clinical data other than an excellent photomicrograph exhibiting the characteristic appearance of the tumor. They remark "While admittedly the cells resemble the oxyphil cells of the parathyroid, they appear to us to resemble even more closely the acidophilic phase occasionally encountered in the thyroid epithelium itself."

Our experience¹ comprises the following two cases.

CASE 11 Bronx Hospital No 38653. A housewife 47 years of age was admitted to the hospital with a history of generalized arthralgias for the preceding 4½ years and a recent history extending over a period of 6 months of cardiac palpitation, tremor, sweating and loss of 40 pounds in weight. The physical examination revealed hypertrophic enlargement and restricted motion of all of the joints. There was a firm nodular enlargement of the right lobe of the thyroid gland. The blood Wassermann test was negative. The routine urine examination was also negative. The white blood count and differential count were normal. The vaginal and urethral spreads revealed no Gram negative diplococci. The basal metabolic rate was +2 per cent.

Following a brief period of lugolization operation was performed. The tumor was found to involve the right lobe of the thyroid gland and was enucleated with such difficulty that a partial excision of the right lobe of the thyroid gland was necessitated together with the tumor.

The specimen was a reddish brown mass of tissue 3 by 2 centimeters in diameter with some evidence of a thin fibrous capsule about the tumor. Microscopic examination revealed adenomatoid areas in a lymphocytic stroma. There were small areas of adenoma malignum or early thyroid carcinoma. The outstanding feature however was the presence of

¹The pathological examination and the report of the microscopic picture of both of our cases was made by Joseph Folio of the Laboratory of the Bronx Hospital. We are indebted to him for his cooperation.

The classification of Haagensen made in 1931 is made from the Memorial Hospital material, is based upon a series of 30 cases, and is as follows.

- 1 Adenocarcinoma
- 2 Small round cell carcinoma
- 3 Giant cell carcinoma
- 4 Papillary cystadenocarcinoma
5. Small alveolar, large cell carcinoma (Hurthle cell type), 2 cases, 6.6 per cent

Perhaps the most inclusive classification is that suggested by Clute and Warren upon an experience of 226 cases

	Cases
1 Adenoma with blood vessel involvement	99
2 Papillary adenocystoma	51
3 Adenocarcinoma (including Hurthle cell adenocarcinoma)	31
4 Fibrosarcoma	3
5 Epidermoid carcinoma	1
6 Giant cell cancer	11
7. Small cell cancer	30

While certain types of neoplasia appear in each classification, there is no unanimity of opinion as to the various forms of cancer which appear within the confines of the thyroid gland, nor, indeed, is there any uniformity of definition regarding the limits of malignancy as the tumors are histologically portrayed

DISCUSSION

One can predict with a reasonable degree of accuracy the future clinical course of many types of carcinoma of the skin, oral mucous membrane, cervix uteri, and certain other tumors on the basis of their histological features. The prognostic and biological significance of, for example, frequent mitotic figures, anaplasia, invasion, staining qualities, cell arrangement, and other features of established value in general oncology are found notoriously inadequate in their application to thyroid tumors. This has led to a great deal of confusion in terminology, which in turn reflects the fundamental confusion in the criteria for pathological classification. To this day there appears no universally accepted classification of thyroid tumors, and the literature is clogged with such ambiguous and noncommittal terms as "benign metastasizing adenoma," "fetal adenoma," "strumas" of various sorts, and "tumors" not definitely

assigned to a benign or malignant category. The lack of a single *fundamentum divisionis* in the classification of thyroid tumors has resulted in the separation of groups of tumors on various bases with consequent overlapping of groups. This has been further complicated by the known wide range of cell morphology in the normal thyroid gland as a result of physiopharmacological changes. In any attempt at a classification of thyroid tumors prime emphasis should be laid upon the benignancy or malignancy of each tumor type. This is at times difficult to determine, but in the last analysis must conform with the clinical course of the disease. If a tumor produces distant metastases it is malignant no matter how benign its histological structure may appear according to our present methods of analysis. This separation into benign and malignant tumors is of greater biological significance than any superficial similarity of cell types in tumors which are in some cases benign and in others malignant. It is because of the difficulty, at times, in establishing a definitive diagnosis of thyroid carcinoma that one is tempted to discard the fundamental basis of dichotomous division into benign and malignant tumors and to classify several tumors together on the basis of a similar cell structure. It was in this way that the Hurthle cell tumor of the thyroid was first described.

In Langhans' cases the fragmentary published data indicates that although there were no microscopic evidences of malignancy in any of the tumors, not even the characteristic invasion of the blood vessels stressed by Graham, 2 of the patients presented metastases with subsequent death. There can be no question but that these 2 cases represented types of thyroid carcinoma. The 3 other cases may have been benign tumors.

We have studied our 2 cases of so called Hurthle cell tumor of the thyroid from this viewpoint and were able to demonstrate in one case that the tumor was accompanied by an area presenting the usual picture of thyroid carcinoma immediately adjacent to the distinctive Hurthle cell form (Fig. 1). We feel that there is no reason to believe that two separate tumors coexisted in the thyroid but

mentioned. At any rate, even if it were conceded that the Hurthle cell tumor which they removed was a functioning parathyroid tumor, one would expect the episodes of tetany to follow rather than to precede the resection of the tumor. Their view is not generally accepted, however, and the similarity to the parathyroid cells is considered by some to be probably purely coincidental.

Getzowa on analogous grounds has claimed that the Hurthle cell tumors arise from the ultimo branchial bodies a view which while held possible by Langhans is considered unwarranted by Wegelin.

Other observers noting the similarity of the cells to the large oxyphilic interfollicular cells described previously by Hurthle, Baber, Langendorff and others, have considered these cells the true anlagen of these tumors and have accordingly classified them as Hurthle cell tumors. Numerous studies of normal thyroid histology have resulted in conflicting opinions as to the nature of this cell and indeed the existence of any type of interfollicular epithelium has been questioned by many observers. Maksimov and Bloom (13) did not find any interfollicular cells in wax plate reconstructions and therefore consider at least some of the so called interfollicular cell groups as tangentially cut follicular wall, a view also held by Rienhoff, Wilson, and Williamson and Pearse, in their careful researches on the minutiae of thyroid structure make no mention of interfollicular epithelium. Nonidez (17, 18, 19) and Raymond have described parafollicular cells in various laboratory animals as has Zechel (26, 27) who considers them as phases in arrangement of the thyroid parenchyma in the cyclic destruction and regeneration of the follicles. Further doubt is cast upon the anatomical identity of these cells by the fact that, although they are of characteristic appearance, all grades of transition have been found between them and the principal thyroid cells (Langendorff). Maksimov and Bloom (14) believe them in all probability to be dead or dying cells. Wegelin considers the oxyphilic cytoplasm and vesicular nuclei as evidences of degeneration as seen in an anemic infarct of the kidney while Minne's opinion is that such

changes represent a stage in the secretory cycle of the normal thyroid epithelial cell.

The evidence at hand then would seem to indicate a physiopathological rather than an anatomical basis for the appearance of the so called Hurthle cell in the normal thyroid. If this is true, then, the so called Hurthle cell is a phase of the thyroid epithelium and as such does not represent a distinct anatomical unit but rather a functional change, probably nutritive. A similar interpretation probably obtains in the tumors of this cell type. This is supported by the observations of Wegelin who on one occasion noted an area of "large cell adenoma" in the center of an otherwise more usual type of thyroid carcinoma with all stages of transition between the larger and smaller cell types. In another case he found scattered areas of large cell formation in an otherwise usual form of *wuchernde struma* while a metastasis which appeared in the forearm several months later exhibited almost exclusively small alveoli with large oxyphilic cells. Clute and Warren have also noted the similarity between these cells and certain involutionary changes following primary thyroid hyperplasia.

CLASSIFICATION OF HURTHLE CELL TUMOR

Because of all of these essentially anatomical and physiological facts the classification of tumors of the thyroid in general and of the Hurthle cell tumor in particular has always been a difficult and controvertible one, and the number of classifications of thyroid tumors is almost as great as the number of students of thyroid pathology. Langhans' classification made in 1905 is based upon an experience of 36 cases and is as follows:

1. Die wuchernde Struma (adenocarcinoma)
2. Karzinomatöse Struma mit dem gewöhnlichen unregelmässigen Bau der Krebse (ordinary form of carcinoma)
3. Metastasierende Kollindstruma (metastasizing colloid goiter)
4. Parastruma Tumor der Epithelkörper oder Glycogen haltige Struma (Kocher) (Tumors containing excessive amounts of glycogen)
5. Papilloma
6. Kankroid
7. Kleinalveoläre grosszelligen Struma vielleicht Struma postbranchialis (Cetzowa) (Small alveolar large cell tumors [Hurthle type?])

Fig 2 Photomicrograph of section of tumor removed from our case, Case 11. Part of the tissue which might indicate malignant changes $\times 45$

Fig 3 In this photomicrograph which is from the same specimen as is Figure 2, is shown the typical Hurthle cell arrangement $\times 75$

Fig 4 Our case, Case 12, showing the typical characteristics of the Hurthle cell large granular cells with large nuclei $\times 75$

Fig. 5. From same specimen as is Figure 4. In this photomicrograph is shown the pervascular arrangement in the Hurthle cell tumor. $\times 75$.

rather than the two portions of the tumor represent different phases of the same process, which, if carried to completion, might have left behind no clue as to the origin of the larger cell type. Stated in another way our interpretation would suppose that the original stimulus to neoplastic formation engendered a thyroid carcinoma, that, with the growth of this carcinoma, new reactive stimuli were effected in the surrounding tissue, that these reactive stimuli, possibly expressed through changes in the vascular supply to the tumor, in turn affected the tumor resulting in a conversion of the histological appearance from that of the more usual type of adenocarcinoma to the Hurthle cell type, that this conversion is a secondary change which may so involve the entire tumor as to leave behind no trace of the original cell type in some cases, and that this new cell type, now representative of the tumor, is not to be considered a distinct form of tumor any more than is the Hurthle cell in the normal thyroid to be considered a fixed anatomical component of the gland. Furthermore this secondary change to the Hurthle type of cell may occur in tumors which originally may have been either benign or malignant, but following the conversion to the Hurthle cell type this difference may no longer be discernible. Accordingly it is readily understood why tumors formerly grouped under the single heading of Hurthle cell tumors may include both benign and malignant types. It is therefore most urgent, wherever possible to search the tumor carefully for remnants of the original unchanged tumor for a clue as to its real malignancy or benignancy. It is only in this way that we may be able to separate individual tumors with this deceptively characteristic histological appearance into their respective benign and malignant categories, which division is from a clinical viewpoint, the most fundamentally important one in the classification of thyroid tumors.

What is the clinical meaning of this secondary change? We believe that the malignancy is not dependent upon the presence of the so called Hurthle cell, but rather on the malignancy of the underlying tumor upon which is superimposed another factor

(possibly nutritive) which is responsible for the conversion of the tumor cells, already either benign or malignant, to the Hurthle form. That this change may modify some of the properties of the tumor we do not deny. If, as we believe, these cells represent a degenerative change, we can expect some decrease in rapidity of growth, and a slightly more favorable prognosis, a view supported by the relatively benign course of even malignant cases.

TREATMENT

In the present state of our knowledge the primary treatment of these tumors is surgical eradication. It seems better to resect the entire lobe than to enucleate the tumor.

RADIATION THERAPY

Experience with radiation therapy is available in the records of Haagensen's 2 cases and in 1 of ours. Haagensen's cases have gone 7 and 11 years respectively since operation and, according to him, have been definitely benefited by x ray therapy. In our case in which a radium collar was applied the effect so far must be correlated with the failure of any metastatic focus to make its appearance, however, it is much too soon for us to make any definite statement with regard to the permanent result. This experience would tend to indicate the great value of radiation therapy in all cases after the tumor has been surgically eradicated.

SUMMARY

- 1 The origin and significance of the Hurthle cell in normal and neoplastic thyroid tissue is indicated.
- 2 Two thyroid tumors with this distinctive cell are presented and the relationship to thyroid carcinoma demonstrated in one of them.
- 3 At the present state of our knowledge, therefore, we consider it advisable not to place too great an emphasis upon the significance of the so called Hurthle cell type of tumor but rather to separate this group into its component benign and malignant categories upon more fundamental criteria. We suggest that the term Hurthle cell tumor be

CONGENITAL ANOMALIES OF THE RECTUM AND ANUS

J. K. BERMAN, M.D., F A C.S., Indianapolis, Indiana

SINCE congenital anomalies of the rectum and anus occur about once in 5,000 newly born babies (3), the average physician will not see a large number of cases. Statistics concerning the frequency of these lesions are extremely variable. Zohrer at the Vienna Lying-In Hospital and Collins in the Dublin Lying-In Hospital jointly report 66,654 deliveries with 3 cases of imperforate anus. These statistics are quoted in Ball's textbook, published in 1887 (1). The Riley Hospital receives children from all sections of the State of Indiana and in the last 12 years there were 34,454 admissions with 22 anomalies of the rectum and anus.¹

The diagnosis of anomaly in this region is not difficult, especially in the serious cases which are associated with, and present symptoms of, acute intestinal obstruction. The difficulty arises in diagnosing the kind of anomaly present so that proper surgical approach may be made.

EMBRYOLOGY

The mesenteron or central portion of the alimentary canal is formed from the entoderm and consists at first of a simple tube which ends blindly anteriorly and posteriorly. This tube represents only the mucous membrane. Later it becomes enveloped in a layer of mesoderm which differentiates into two portions—the outer forming the peritoneal covering while the inner forms the muscle and connective tissue elements. An invagination of ectoderm takes place later at the two ends, anteriorly the stomodeum which constitutes the mouth and posteriorly the proctodeum which constitutes the anal orifice. If we briefly refer to the diagram (Fig. 1) we see that in the 5 weeks embryo the intestine and urogenital sinus empty into a common opening which is known as the cloaca. This condition is nor-

mally present in certain birds and in certain fowls. It is really a caudal expansion of the hind gut which gives off in front of the allantoic stalk (bladder).

At 6 weeks the saddle-like partition between the intestine and the allantois, and known as the urorectal septum, grows caudally, dividing the cloaca into a dorsal rectum and a ventral primitive urogenital sinus. This is complete at about 9 weeks. In the male this latter structure gives rise to the bladder and a greater portion of the urethra, all but the anterior part, and above and posteriorly it receives the mesonephric ducts which later become the vasa deferentia. In the female the muellerian ducts which are derivatives of the aforementioned, later become the uterus and vagina.

The perineum develops by the division of the cloacal membrane into the urogenital membrane in front and the anal membrane behind and by a down growth and spreading out of the mesenchymal elements between these two membranes. At 6 weeks the coccygeal eminence is very prominent and in front of it is a slight elevation surrounded by a groove. From this will develop the anus and generative organs (Fig. 1). At 8 or 9 weeks the anus is separated from the cloacal opening and the perineal septum has begun to form. At 10 weeks determination of sex is possible and the anus is separated from the anterior perineum. This separation is so complete that extravasation of urine is limited to the front of this space and abscesses connected with the rectum seldom invade the front portion. A small pit forms in the perineum (proctodeum) which folds inward until it joins the hind gut. This infolding occurs when the membrane separating them and known as the anal membrane ruptures. This takes place about the eighth week of pregnancy and the point of junction corresponds to what is known as the white line of Hilton in the adult.

From the Surgical Service of the James Whitcomb Riley Hospital and the Department of Surgery, Indiana University School of Medicine, Indianapolis

¹The 23d case was in the Coleman Hospital

discarded and that it be replaced by the terms adenoma with Hurthle cell change and adenocarcinoma with Hurthle cell change

Fig 3 A, Clinical appearance of perineum. Note absence of anus and incomplete development of genitalia. B, Roentgenogram, retouched, showing upside down position. After massage under fluoroscope air pocket was found to descend to a lower level. C, Injection of sodium

iodide into bladder. Note its unusual shape and the abnormal ureters. D, Injection of sodium iodide through recto-urethral fistula into hind gut. E and F, Diagram of recto-urethral fistula before and after operation. Case R-18960 S S.

According to Fraser the congenital malformations of the anus are as follows:

1. Congenital narrowing of the anal canal.
2. Congenital occlusion of the anal canal, by fibrous or membranous tissue, the occlusion being partial or complete.
3. Abnormal location of the anus.
4. Congenital absence of the anus.

Whereas the congenital malformations of the rectum are:

1. Total absence of rectum.
2. Atresia of the lower end of the rectum.

3. Membranous occlusion of the rectum

4. Rectovaginal, recto-urethral and rectovesical fistulas. This classification is accurate anatomically, but does not lend itself well to clinical application because combinations are the rule. A better grouping for practical purposes is the one suggested by Ladd and Gross which is as follows (Fig. 2):

1. Incomplete rupture of the anal membrane or stenosis at a point 1 to 4 centimeters above the anus. Repeated rectal dilatations is all that is necessary.

Fig. 1 Diagram of embryological development. Division of the rectum and urogenital diaphragm in the early embryo. Inset: method of inversion of proctodeum and descent of hind gut.

TYPES OF MALFORMATIONS

Most malformations are an arrested development or irregular growth of the proctodeum or the mesenteron. Frequently there is a failure of closure of the perineal septum and then the various forms of fistulas occur. It may readily be seen that anomalies may occur involving the rectum, the anus, the urogenital tract, or any combination of these structures. Many classifications have been advanced to cover all varieties of malformation. Perhaps the most complete and earliest of this group will be found in Ball's textbook.

1. Preternatural narrowing of the anus at the margin, occasionally extending some distance above this point.

2. Complete occlusion of anal aperture by simple membrane or common integument.

3. No anus whatever, the rectum being partially deficient and terminating in a cul de sac at a greater or less distance above its natural outlet.

4. The anus in this variety is normal, the rectum at a variable distance above it being either obstructed by a membrane or completely occluded for a greater or less distance.

5. The anus opens at some part of the perineal or sacral region instead of at its normal position.

6. The rectum opens into the bladder, urethra or vagina, sometimes forming a complete cloaca, the normal anus usually being absent.

7. Rectum normal with the exception that either the ureters, the vagina, or uterus, open preternaturally into it.

8. The rectum is entirely wanting.

9. The rectum and colon both absent. In these cases there is sometimes an opening leading to the intestine at some other part of the surface of the body. It will be seen that in the first three varieties the development of the proctodeum is principally at fault, while in the others the malformation is of a more complicated character.

Fig. 2 Left four types of anomalies which have been encountered.

Center types of fistulas in male (A) rectovesical (B) recto-urethral (C) rectoperineal.

Right types of fistulas in female (A) rectovesical (B) rectovaginal (C) rectofossa navicularis and rectofourchette (D) rectoperineal (Modified from Ladd and Gross loc. cit.)

fetal enteritis (4) may be the cause. One thing is definitely known—that these anomalies usually do not occur singly and this must be borne in mind in prognosis and treatment.

SYMPTOMS OF ANOMALIES

The symptoms of most of these patients are those of acute intestinal obstruction. Sometimes there is partial intestinal obstruction with distention and in the fistulous types parents will note that there is an abnormal opening with an absence or occlusion of the anus. Further discussion is unnecessary for diagnosis is made easily when the possibility of these congenital anomalies is considered.

DIAGNOSIS OF TYPES

The chief concern of the surgeon is the accurate diagnosis of the type anomaly that exists. In order to establish this many methods are used, such as:

1. X-ray examination of the abdomen with the child in the upside down position (9). The rationale for this is the hope that gas in the obstructed hind gut will rise to the top or dome of the obstruction, thereby revealing its proximity to the anal canal. This method is a very useful one, but leads to errors in diagnosis during the first 24 hours of life because gas is rarely present beyond the hepatic flexure (Fig 3).

Fig 6 A, Photograph of anomaly present. Note the rectofossa navicularis fistula (retouched). B, After operation. Note double vagina and reconstructed perineum. Case C-R-5583. J. R.

2. Injection of 12½ per cent sodium iodide when there is an external fistula (Fig 3); this should be done also to reveal internal fistulas.

3. Performance of a colostomy with digital examination of the blind hind gut. This method is fraught with danger because the mortality in this group is extremely high (some figures up to 90 per cent).

4. We have recently used the fluoroscope as an aid in diagnosis, especially in the first

Fig 9

Fig 9 Photograph of rectoperineal fistula. Note persistence of genital tubercles or swellings. Case R-19119. G. R.

A

B

2 Imperforate anus or obstruction due only to a persistent membrane. Cruciate incisions followed by dilatations is all that is necessary.

3 Imperforate anus with rectal pouch separate from anal membrane. (Most frequently encountered anomaly.) Perineal incision is required and rectal pouch should be brought down to anal sphincter.

4 Anus and anal pouch normal, but rectal pouch ending blindly. Most difficult to treat because the rectal pouch is so high that it is difficult to reach through perineal approach, mortality, 61.6 per cent.

C

Fig 4 A Before operation. Note enormous distention. B After operation. C Diagram indicating anomaly encountered. Rectovaginal fistula running between septum in double vagina. Case R 15694. A. H. K.

If now we add to this classification the various types of fistulas we have a satisfactory clinical grouping. By referring to the embryological review we may readily understand why in the male there may be rectovesical, rectourethral, or rectoperineal fistulas, whereas in the female there may be rectovesical but more commonly rectovaginal or rectovulvar or rectoperineal fistulas (Fig 2).

CAUSE OF ANOMALIES

The cause of these anomalies is of course, a matter of conjecture. Some say it is apt to occur in families (6). Others have said fetal peritonitis or chorionic adhesions as well as

Fig 5 A Diagram showing rectoperineal fistula. Sphincteric action present in both openings. B Diagram of cross section.

brought down to the skin, a hollow needle is inserted to make sure of the structure and then a cross incision is made and the mucous membrane sewed to the skin in a position corresponding approximately to the anal sphincter. Chromic catgut No. 0 is used to suture the bowel to the skin as well as to close the incision.

4 If a fistula is present, it should be left alone until the child is older. This is done because attempts to close them at the time of operation fails in half the cases and increases the mortality. In older children fistulas may be closed if accessible, but if in the bladder closure should be deferred until the child is much older, also, fistulas sometimes, although very rarely, will close spontaneously after the rectal opening is re-established. If the child is unable to stand any surgery, then simple dilatation of the fistula may be used temporarily.

SUMMARY OF CASES

Of the 23 cases, there were 12 males and 11 females. One of doubtful sex (Fig. 3) was thought to be a female, but diagnosed a male because of structures which felt like testes in

the genital folds and a urethra which traversed the genital tubercle. So far as I am able to ascertain the urethra has never been reported in the clitoris.

Six were in the newborn, 10 under 1 year, 4 between the ages of 1 and 5 years, and 3 over 5 years of age.

Fourteen had associated fistulas, 9 did not. Following our grouping there were 2 in group 1; 2 in group 2, 2 in group 3; 3 in group 4, and 14 (60 per cent) in group 5.

Thirteen (56.5 per cent) of these patients had associated anomalies. Two of these had four present. Nature does not err singly in most cases (Table I).

Five patients were treated by palliation or were *in extremis* before surgical treatment could be instituted. Of this group 3 died and 2 were unimproved, a mortality of 60 per cent.

Eighteen were treated surgically. There were 3 deaths in this group and an operative mortality of 6.6 per cent. A follow-up study

Fig 10 Diagram illustrating stones in the neck of the bladder and rectovesical fistula with diverticulum containing a urinary calculus Case R 18,8 D D

24 hours of life The infant may be moved in various positions and by gentle massage of the abdomen gas is forced down or up into the blind hind gut The position is then marked by bony landmarks or by metal arrows fastened to the skin by adhesive Thus far we have had no inaccurate diagnosis by this method¹ The fluoroscope often reveals co-existent anomalies by demonstrating pockets of gas which cannot be shifted from one portion of the intestine to another

TREATMENT

Treatment obviously varies with the type anomaly and the age of the child We may

¹The author is indebted to Dr Wright of our x-ray department for his aid in developing this procedure

dogmatically state the following rules concerning treatment

1 All treatment depends upon accurate diagnosis

2 Avoid colostomy whenever possible Mortality in this group is high, especially in the newborn

3 Dissections should be made from below by making a longitudinal incision from the middle of the perineal body posteriorly to the coccyx, thereby cutting directly through the sphincter Since the external anal sphincter muscle develops from regional mesenchyma and is not dependent upon the presence of the terminal bowel it is practically always present This accounts for good sphincteric control in patients operated upon for congenital absence of anus The rectum descends in the hollow of the sacrum closely applied to that bone and except at its upper part is uncovered by perineum posteriorly In front the perineal pouch descends to a much lower level while its close relations to the genito-urinary organs should be borne in mind Dissection should then be carried upward hugging the coccyx and the hollow of the sacrum, staying in the midline Extreme gentleness and care are necessary until a structure resembling membrane is encountered since this may be peritoneum it should be gently pushed back anteriorly The operation is carried on under local anesthesia in the newborn, and as the baby cries and strains the hind gut is seen to bulge into the field of operation After mobilization is complete the hind gut is

Fig 11 Left and center infant 6 weeks old with rectofourchette fistula before operation Right case of rectofossa navicularis fistula in an infant 3 months of age 5 weeks after perineal operation

R-5149, D. L. D., male, aged 2 days; full-term child, breech delivery, birth weight $7\frac{1}{2}$ pounds. The parents noted that the baby had no bowel movements and that he vomited. Physician made diagnosis of imperforate anus and the child was admitted to Riley Hospital on January 24, 1933. He was operated upon immediately. Skin incision was made through the approximate site of the anus. Tissues were dissected back, and the sac of the hind gut was exposed. This was opened and sutured to the skin margins forming an anus. Much meconium was passed. The infant did well for a period of 4 days after operation when he suddenly became cyanotic and physical and x-ray examination definitely determined that there was a partial collapse of the left lung field, diagnosed as atelectasis neonatorum. Oxygen therapy was instituted; however the patient died on January 31, 1933. Post-mortem examination disclosed imperforate anus, Meckel's diverticulum, and atelectasis of left lung.

GROUP IV

Ball: Anus normal, rectum at a variable distance above obstructed by membrane or completely occluded for a greater or less distance.

Ladd and Gross. Anus and anal pouch normal. Rectal pouch ending blindly.

R-12224, J. G., female, aged 2 days, normal delivery, full-term baby, birth weight 8 pounds. Mother noticed that the patient did not have a bowel movement and the physician made the diagnosis of imperforate anus and referred the child to the Riley Hospital. Admission was February 17, 1935. A dimple was found about the region of the anal orifice and a slight protrusion was noticed when the baby cried. Incision was made in this area and with blunt dissection the subcutaneous tissue was pushed back with a hemostat until the hind gut was reached which was approximately 2 centimeters from the skin. The hind gut was opened at which time a large amount of gas and meconium was expelled. The hind gut was loosened and pulled down with four clamps. It was then sutured to the skin with interrupted plain catgut No. 1 sutures. No anesthesia was used and the patient was in good condition following operation. On April 13, 1935, patient was readmitted. Diagnosis of scar tissue contracture resulting in imperforate anus was made. After repeated dilatations the patient was discharged on April 13, 1935, in an improved condition. Associated anomalies mongolian idiocy. (See Fig. 7.)

R-16305, M. E. J., male, aged 2 days, admitted May 20, 1936. Shortly after birth, which was a breech presentation, the child began to vomit. Vomiting was projectile in type and stercoraceous in character. There had been no stools. The baby was cyanotic and the abdomen markedly distended. A slight anal dimple was found, but there was com-

plete atresia of the rectum. X-ray examination showed the hind gut to be a short distance above the occluded anus. The child was immediately transfused, he received 70 cubic centimeters of citrated blood. However, before the child could be prepared for surgery, he died and an autopsy was obtained. This revealed a congenital atresia of the anus and descending colon at the rectosigmoid junction, and an occlusion of the hind gut. Associated anomalies: patent ductus arteriosus, patent foramen ovale, cryptorchidism, bilateral

GROUP V

Ball: Rectum opens into bladder, urethra or vagina sometimes forming a complete cloaca, the normal anus usually being absent or

Author: Fistulas in combination with any of previous groups. Most common type of anomaly in our series.

R-6441, M. P., male, aged 10 years, premature child 8 months, weight 5 pounds. Diagnosis of imperforate anus made at birth and perineal operation performed at 30 hours bringing hind gut down to anal orifice with recovery. Child's mother noticed bluish discoloration of the nails at 5 weeks and a congenital heart lesion was demonstrated at this time. At 6 months feces was seen to come through penis. Child was next seen at the age of 4, and a definite rectovesical fistula was demonstrated. Now at the age of 10 sphincteric control is present although not strong. Urine occasionally is loaded with pus and *Bacillus coli* demonstrated but soon cleared up after bladder irrigations. Congenital heart lesion present, since bladder condition was controllable, no further surgery was done. Child has been a cardiac invalid. Last seen April 17, 1937.

R-1878 D. D., aged 2 years, male, was born without anal opening. At 26 days a perineal operation was done elsewhere and the rectum brought down to the skin. At 1 year of age a colostomy was attempted elsewhere. However, the small bowel was entered and an enterostomy was performed instead. This soon closed. On admission to the Riley Hospital on April 19, 1932, the child was found to have a small anal opening with no sphincteric control, and in addition a rectovesical fistula. The urine was contaminated with fecal matter. Cystoscopic examination was done on May 26, 1932, and kidney, ureter, bladder plate showed the presence of multiple calculi in the urinary bladder. Intravenous pyelogram revealed dilatation of the right ureter and apparently no functioning of the left kidney. X-ray plates of the lumbosacral spine showed a spina bifida occulta of the first two sacral segments. Retrograde cystogram disclosed a definite fistulous tract between the bladder and the rectum. Surgery on June 23, 1932, was as follows: "Midline incision extending from pubis well up toward the umbilicus. Fascia divided and bladder exposed by blunt finger

of these cases showed that 5 others had died since their release from the hospital

This brings the total deaths to 11 or 47.8 per cent over a period of 12 years (Table II). In 8 (72.8 per cent) of these deaths associated anomalies were present which accounted for their demise.

GROUP I

Ball Preternatural narrowing of anus at margin occasionally extending some distance above this point

Ladd and Gross Incomplete rupture of anal membrane or stenosis at a point 1 to 4 centimeters above the anus

R 5383 L. G. male aged 4 years full term baby. At 1 month his weight was 6 pounds. The child had attacks of colic which persisted as severe abdominal cramp like pains. He had infantile paralysis at 2½ year of age. There was no control of bowel action. Diagnosis of Hirschsprung's disease was made elsewhere. Our examination showed a constriction of the anus about 3½ inch above the external sphincter. This was hard and unyielding, with fecal impaction above. On October 3, 1933, the stricture was divided by cauterization and followed by repeated dilatations. Last seen on May 7, 1935 when anus was open and there was no fecal impaction. The mother was instructed to continue dilatation.

R 9191 R. D. D. male aged 2 months full term normal delivery birth weight 8¼ pounds. At 3 weeks of age he had projectile vomiting. He was given a formula and atropine which helped some but he lost weight. He was admitted to Riley Hospital on August 29, 1934 with diagnosis of imperforate anus (group I), bilateral club feet and deformity of the back. Treatment was symptomatic and supportive but his condition became progressively worse and he died on September 16, 1934. Postmortem examination disclosed congenital partial absence of vertebrae, talipes equinovarus, imperforate anus, absence of left kidney, acute suppurative otitis media, acute mastoiditis, infectious gastroenteritis and Bacillus coli septicemia.

GROUP II

Ball Complete occlusion of the anal aperture by simple membrane or by common integument

Ladd and Gross Imperforate anus or obstruction due only to persistent membrane

R 7915 B. J. H. male aged 17 months full term baby. An imperforate anus was discovered at birth. The anal membrane was opened and the stricture was dilated on four occasions. On January 15, 1934 a perirectal abscess was drained which left a fistula

in ano. No further surgery was done and no further symptoms were reported. On March 19, 1934 the child was readmitted to the hospital with the diagnosis of chronic otitis media and mastoiditis. A mastoidectomy was done. Child died April 8, 1934 of infectious diarrhea. No associated anomalies.

R 13595 C. L. female aged 3 days premature birth. Soon after birth the physician noted an imperforate anus with marked distention. Upon admission to the Riley Hospital on July 24, 1935 the distention was very marked and the child was not voiding. She was vomiting and her condition was very critical. She was placed in the oxygen chamber and was given fluids subcutaneously. A small incision was made through the anus and a large quantity of gas escaped through the tube. No further operative procedure was done because of the critical condition of the patient. She died on July 25, 1935. No postmortem examination was made. Associated anomalies were in the urinary tract.

GROUP III

Ball No anus whatever the rectum being partially deficient and terminating in a cul de sac at a greater or less distance above its normal outlet

Ladd and Gross Imperforate anus with rectal pouch separate from anal membrane

R 10895 L. A. male aged 17 months full term baby, birth weight 8¼ pounds. Forty eight hours after birth it was noted that there was a congenital absence of the anus. The child was taken to the hospital immediately (elsewhere) and operated upon. Colostomy was performed and following surgery the child improved. He was admitted to the Riley Hospital on October 2, 1934. Diagnosis of imperforate anus was made. A ray examination with barium showed good filling of the large intestines to the level of the colostomy, but no barium went below this area. A ray did not demonstrate a sigmoid or rectum near the normal location. The child was sent home on October 31, 1934 and was readmitted on April 23, 1935 for surgery but this procedure was not done because the ward was isolated for scarlet fever. He was furloughed on May 8, 1935 to return in 3 weeks. However he was not brought back at that time. Associated anomalies none.

R 13986 J. W. male aged 3 months full term infant weight 8 pounds 11 ounces breech extraction. At birth the physician noted that there was a congenital absence of the anus. The baby was operated upon July 6 elsewhere and a colostomy was done. He was admitted to the Riley Hospital on September 14, 1934. Upon admission the child was markedly dehydrated and the only treatment was repeated blood transfusions which were unavailable. The child died on September 23, 1934. Diagnosis imperforate anus with rectal pouch separate from the anal membrane. Associated anomalies patent ductus arteriosus.

R-5149, D. L. D., male, aged 2 days; full-term child, breech delivery; birth weight 7½ pounds. The parents noted that the baby had no bowel movements and that he vomited. Physician made diagnosis of imperforate anus and the child was admitted to Riley Hospital on January 24, 1933. He was operated upon immediately. Skin incision was made through the approximate site of the anus. Tissues were dissected back, and the sac of the hind gut was exposed. This was opened and sutured to the skin margins forming an anus. Much meconium was passed. The infant did well for a period of 4 days after operation when he suddenly became cyanotic and physical and x-ray examination definitely determined that there was a partial collapse of the left lung field, diagnosed as atelectasis neonatorum. Oxygen therapy was instituted, however the patient died on January 31, 1933. Post-mortem examination disclosed imperforate anus, Meckel's diverticulum, and atelectasis of left lung.

GROUP IV

Ball. Anus normal, rectum at a variable distance above obstructed by membrane or completely occluded for a greater or less distance.

Ladd and Gross. Anus and anal pouch normal. Rectal pouch ending blindly.

R-12224, J. G., female, aged 2 days, normal delivery, full-term baby, birth weight 8 pounds. Mother noticed that the patient did not have a bowel movement and the physician made the diagnosis of imperforate anus and referred the child to the Riley Hospital. Admission was February 17, 1935. A dimple was found about the region of the anal orifice and a slight protrusion was noticed when the baby cried. Incision was made in this area and with blunt dissection the subcutaneous tissue was pushed back with a hemostat until the hind gut was reached which was approximately 2 centimeters from the skin. The hind gut was opened at which time a large amount of gas and meconium was expelled. The hind gut was loosened and pulled down with four clamps. It was then sutured to the skin with interrupted plain catgut No. 1 sutures. No anesthesia was used and the patient was in good condition following operation. On April 13, 1935, patient was readmitted. Diagnosis of scar tissue contracture resulting in imperforate anus was made. After repeated dilatations the patient was discharged on April 13, 1935, in an improved condition. Associated anomalies: mongolian idiocy. (See Fig. 7.)

R-16305, M. E. J., male, aged 2 days, admitted May 20, 1936. Shortly after birth, which was a breech presentation, the child began to vomit. Vomiting was projectile in type and stercoraceous in character. There had been no stools. The baby was cyanotic and the abdomen markedly distended. A slight anal dimple was found, but there was com-

plete atresia of the rectum. X-ray examination showed the hind gut to be a short distance above the occluded anus. The child was immediately transfused, he received 70 cubic centimeters of citrated blood. However, before the child could be prepared for surgery, he died and an autopsy was obtained. Associated anomalies: patent ductus arteriosus, patent foramen ovale, cryptorchidism, bilateral

GROUP V

Ball. Rectum opens into bladder, urethra or vagina sometimes forming a complete cloaca, the normal anus usually being absent, or

Author. Fistulas in combination with any of previous groups. Most common type of anomaly in our series.

R-6441, M. P., male, aged 10 years, premature child 8 months, weight 5 pounds. Diagnosis of imperforate anus made at birth and perineal operation performed at 30 hours bringing hind gut down to anal orifice with recovery. Child's mother noticed bluish discoloration of the nails at 5 weeks and a congenital heart lesion was demonstrated at this time. At 6 months feces was seen to come through penis. Child was next seen at the age of 4, and a definite rectovesical fistula was demonstrated. Now at the age of 10 sphincteric control is present although not strong. Urine occasionally is loaded with pus and *Bacillus coli* demonstrated but soon cleared up after bladder irrigations. Congenital heart lesion present, since bladder condition was controllable, no further surgery was done. Child has been a cardiac invalid. Last seen April 17, 1937.

R-1878, D. D., aged 2 years, male, was born without anal opening. At 26 days a perineal operation was done elsewhere and the rectum brought down to the skin. At 1 year of age a colostomy was attempted elsewhere. However, the small bowel was entered and an enterostomy was performed instead. This soon closed. On admission to the Riley Hospital on April 19, 1932, the child was found to have a small anal opening with no sphincteric control, and in addition a rectovesical fistula. The urine was contaminated with fecal matter. Cystoscopic examination was done on May 26, 1932, and kidney, ureter, bladder plate showed the presence of multiple calculi in the urinary bladder. Intravenous pyelogram revealed dilatation of the right ureter and apparently no functioning of the left kidney. X-ray plates of the lumbosacral spine showed a spina bifida occulta of the first two sacral segments. Retrograde cystogram disclosed a definite fistulous tract between the bladder and the rectum. Surgery on June 23, 1932, was as follows: "Midline incision extending from pubis well up toward the umbilicus. Fascia divided and bladder exposed by blunt finger

dissection Bladder opened and two stones removed from the posterior urethra A third stone was not found in the bladder It was located outside of the bladder cavity Its size was approximately 1 by $\frac{3}{4}$ inch freely movable and could be felt from within the bladder wall on any side and could be brought down to neck of the bladder It was smooth and flat on one side The bladder was freed on the left but the stone was not attached in this region On rectal examination the stone could also be felt outside the gut and outside the bladder The bladder was anchored to the abdomen with silk, a piece of gauze was inserted above and below and a Pezzer siphon tube was anchored in the bladder The skin was closed with silk worm gut Patient left the operating room in good condition Proctoscopic examination revealed a small fistulous tract about 1 inch above the strictured area in the rectum The stricture was dilated and the child was dismissed on August 19, 1932, to return for future dilatations It was felt that the child would not be benefited by surgical closure of the fistulous tract at this time Follow up disclosed that the child died in 1937 An autopsy revealed congenital atresia of the rectum rectovesical fistula and a stone in a diverticulum of the fistulous tract (Fig 10)

RECTOVAGINAL FISTULA

R 1569, A H K female aged 7 weeks full term baby of syphilitic mother—three siblings (2 still born 1 died at 1 week) 1 miscarriage When 7 weeks old there was an enormous abdominal distention general emaciation but no vomiting Diagnosis imperforate anus re- to aginal fistula Operation was done March 18, 1936 Hind gut was brought down to the skin through a perineal incision after perineum was divided Double vagina was divided and the perineum reconstructed Recovery followed operation Repeated dilatations were done Last seen November 22, 1936 Good progress had been made On December 13, 1936 seen by Dr K. of Laporte, when there was obstruction due to intussusception at the iliocecal valve Baby died before surgery could be instituted (Fig 4)

R 1507 J A G female aged 6 weeks slightly premature normal delivery birth weight 6½ pounds On the day after birth it was noted that the bowel movement was through the vagina An anal dimple was present but there was no opening Baby was in good nutritional state upon admission on December 17, 1935 Diagnosis was imperforate anus and congenital rectovaginal fistula No surgery was attempted because of the infant's poor condition and treatment was supportive and symptomatic Patient gradually grew worse and died on April 10, 1936 Postmortem examination showed bronchopneumonia otitis media congenital imperforate anus and rectovaginal fistula

R 1662 M A female aged 4 months born August 20, 1930 full term, normal delivery On the second day after birth the mother noticed that the child had had no bowel movement and examination

of the perineum revealed that no anus was present A small amount of fecal matter was coming through the vagina The family doctor then dilated the rectovaginal fistula and the baby managed to thrive with the condition until admission to the Riley Hospital on December 14, 1930 Diagnosis in the hospital was rectovaginal fistula with congenital absence of anus On April 15, 1931, under ether anesthesia perineal incision was made the vaginal canal and bowel opening identified and the rectum dissected away from the vaginal floor A muscular band was found just below the fourchet which had the resemblance of sphincter fibers With blunt dissection an opening at the approximate site of the anus was made and the rectum brought down through this and sutured to the cutaneous margin with plain catgut No 0 The skin incision and lower part of the vaginal floor were closed with interrupted sutures of plain catgut No 0 Following this operation the sutures pulled out and a second operation was done on April 21, 1931 Rectum was again brought down to the new opening made at the first operation and anchored with continuous sutures of black silk interrupted at three places Vaginal mucosa was anchored at the cutaneous margin with interrupted sutures of plain catgut No 0 Following this procedure repeated rectal dilatations were done The patient was discharged on June 12, 1931 and was last seen on June 25, 1934 with marked improvement No associated anomalies were recorded

R 5242, M McC female aged 7 months normal delivery Shortly after birth attending physician noted the absence of an anus and that fecal matter was exuding from the vagina The patient seemed to thrive in spite of this anomaly until February 4, 1933 when she was admitted to the Peley Hospital because of distention Our diagnosis was congenital narrowing of the anus with rectovaginal fistula Repeated dilatations were done and the patient made a satisfactory recovery Last seen in the out patient department on February 17, 1936 with satisfactory progress noted

R 3156 G C female aged 7 months full term normal delivery At birth physician noted that the anus was imperforate and that fecal matter exuded from the vagina The fistulous tract was dilated and the child seemed to thrive until her admission to the Riley Hospital on April 25, 1937 with bronchopneumonia No operative procedure was done except for dilatation of the rectovaginal fistula The parents were asked to return the child for surgery at a later date but this has not been done therefore the present status of the child is unknown A letter received November 8, 1937 reported that she had been feeling well and was gaining weight and that the family had moved to Illinois

RECTOVAGINAL AND RECTO URETHRAL FISTULA

R 15092 J M S, female aged 6 months full term baby No abnormality was noted by physician at birth When 8 days old mother noted bowel ac

tion through vagina and absence of anus Insertion of two opaque catheters and injection of opaque media showed the posterior catheter to lead into the rectum and the anterior catheter into a small bladder. There was then a recto-urethral as well as recto-vaginal fistula, but the latter was much larger and all fecal matter discharged through it No treatment was done by staff at this time A small umbilical hernia was present Last seen April 27, 1936, in good condition

RECTOVAGINAL AND RECTOPERINEAL FISTULA

C-8656, S. U., female, aged 19 years Patient was seen in Prenatal Clinic at the Coleman Hospital where general physical examination had failed to disclose the congenital malformation of the rectum She was admitted to the hospital on December 21, 1935, in labor. On admission it was noted that rectal examination was impossible because the rectal opening was too small to admit a finger She was allowed to continue in labor, and after 15 hours the head was no farther than mid-pelvis by abdominal examination. Vaginal examination was therefore done and disclosed that the middle finger accidentally entered an unseen opening and the index finger entered the vagina. Closer examination revealed this opening to be about midway between the hymenal ring and the true anus, and easily admitted a finger There was a moderate degree of sphincter action about this opening Previous to this nurses had reported that rectal ether, which had been given through a catheter into the rectum through the anus, had come out of the vagina The anomalous opening was invisible to ordinary examination due to the peculiar way in which the mucous membrane was overlapped and folded Further history at this time revealed that the patient had been born with a very small anal opening At 1 year of age excision of the fistula was attempted elsewhere A few days after operation, however, the stitches had torn loose and since that time no treatment had been instituted. Patient was delivered by cesarean section No treatment of fistula done at this time The patient has not been seen since her discharge from the hospital.

This demonstrates that sphincteric action is possible even when the rectum is not situated in the normal position (Fig. 5).

RECTOVAGINAL (FOSSA NAVICULARIS) FISTULA

R-5583, J. R., female, aged 9 years, full-term, normal delivery Malformation was first noted when child was 5 months of age, but she was not ill up to the time of admission to the Riley Hospital on February 24, 1930 Diagnosis imperforate anus, rectovaginal fistula, hydrocephalus After consultations and examination it was decided to readmit the child in 1 year for operation if her condition warranted it, and the hydrocephalus had not increased. She was readmitted on March 20, 1933, having had no disease, except pertussis, since the last admission She was again furloughed without operation, but

was readmitted on April 13, 1937, at age of 7 years. She was operated upon April 29, 1937. Incision was made in the region of the anal dimple. The hind gut was found to extend into the fossa navicularis. A transverse incision was made freeing this portion of the vagina together with the hind gut. This structure was then anchored to the skin in the normal position of the anus. The perineum was then reconstructed The child was found to have a double vagina, also. Following surgery the enormous fecal impaction was released by using peroxide irrigations Associated anomalies: cross eyes, double vagina (Fig. 6).

RECTOVAGINAL (FOURCHETTE) FISTULA

R-2736, N. S., female, aged 9 years Soon after birth it was noted that the child had a small opening just posterior to the fourchette (frenulum labiorum pudendi) A small amount of fecal matter was seen to exude at this point which was anterior to the rectal sphincter. The patient was operated upon (elsewhere) and simple dilatation of the fistula was done. On August 31, 1936, the patient was operated upon at the Riley Hospital by the perineal route, and the hind gut was brought down to the skin margin. On September 15, 1936, the fistula was excised but later recurred Following this the patient had repeated rectal dilatations. When she was last heard from the rectofourchette fistula was still present, but the newly formed anus was functioning with good sphincteric control (Fig. 8).

RECTO-URETHRAL FISTULA

R-5423, P. S., male, aged 12 hours; full-term baby Child was brought to the Riley Hospital because of an imperforate anus, and was operated upon March 2, 1933 Through a perineal incision the blind hind gut was brought down to the skin and anchored with interrupted silk sutures The child passed meconium, but expired on March 4, 1933. Postmortem was obtained with the findings of imperforate anus, recto-urethral fistula, congenital atresia of the right iliac artery.

R-18960, S. S., female (?), aged 1 day; full-term baby, normal delivery, weight 7 pounds. Physician noted at birth the absence of an anus and malformed genitals. Numerous roentgenograms, including sodium iodide injection, revealed absence of anus, blind hind gut with a recto-urethral fistula The child was operated upon March 12, 1937, by perineal section The blind hind gut was identified, found $1\frac{1}{4}$ inch from the skin margin. It was carefully mobilized, brought down to the skin, opened, and the free edges were sewed to the skin with interrupted plain catgut No ∞ sutures. The hind gut was then flushed with normal saline solution and a large amount of meconium was recovered The child made an uneventful recovery, and after several manual dilatations he was dismissed from the hospital in good condition on April 28, 1937 Before the baby left the hospital several urinalyses were made and the genito-urinary department was

asked to see the child. The abnormal ureters and bladder indicated clearly the congenital malformation of the urinary tract with infection. However no treatment was instituted at this time. On May 1, 1937, a letter was received from the physician stating that the baby had died from possible urinary infection. Associated anomalies were in the genito-urinary tract (Fig. 3).

R 19119 G R., male aged 9 weeks full term child normal delivery entered the Riley Hospital on March 29, 1937. The complaint was inability to have normal stools and the presence of a skin tab about the rectum. Diagnosis was incomplete rupture of the rectal membrane with a stenosis, together with a congenital failure of the proctodeum to invert. At operation the hind gut was found to be constricted and to have several small openings which formed draining sinuses about the constricted anus. The operative procedure was as follows: The area around the small sinuses was excised dissecting in ward approximately 5 centimeters where the hind gut was entered and a large amount of hard fecal material was expelled by the patient. The colon was then irrigated thoroughly and the hind gut was sutured to the skin giving a good external opening. Associated anomalies none (Fig. 9).

CONCLUSIONS

1. A study of 23 cases of congenital anomalies of the rectum and anus has been made and a brief summary of each case is recorded. This type of anomaly is rare.

2. In over 56 per cent of these cases there were one or more associated anomalies. This

Since submitting this paper for publication we have treated 3 more cases. One with narrowing of anus and rectum for a distance of 1 1/2 in. (Gro. p 1). A girl aged 3 years who complained of partial fecal incontinence. She had an enormously distended sigmoid flexure for 1 1/2 in. After 2 days of treatment with enemas and cathartics the rectum was opened and the sigmoid was removed. The patient is doing well with complete recovery (Fig. 1). On female infant aged 6 weeks with ectofoveollette fistula (Group V) having perineal operation with complete recovery. The latter 2 cases were associated with congenital absence of the anus.

proves the wisdom of an old aphorism "If you find one congenital anomaly search for others."

3. The simplest classification is the combined clinical one as suggested.

4. It is necessary to make a careful study of the type anomaly so that correct treatment may be applied. The aid of the fluoroscope in the newborn is described.

5. A study of the various methods of treatment and their results leads one to conclude that early perineal operation is the method of choice.

6. Sphincteric action may be obtained even if the hind gut is not implanted within the anal sphincter or if this sphincter is absent.

THE USE OF OS PURUM IN BONE IMPLANTATIONS

With Special Reference to Its Use in Tuberculous Bone and Joint Lesions

SVANTE ORELL, Stockholm, Sweden

IN MY thesis published in 1934,¹ I reported the results of some investigations I had made on the treatment of tuberculous spondylitis, in which small pieces of bone were implanted in the wound over the tibia during the performance of operations to obtain fresh bone for spinal fusions according to Albee's technique. The implanted pieces of bone were removed for gross and microscopic examination after varying periods of time. Repeated x-ray pictures were also taken of the pieces of bone while they still lay in the tissues.

By these investigations, I was able to show that if a fresh autoplasmic bone transplant were laid subcutaneously, and another were boiled and laid subperiosteally upon the tibia, newly formed bone tissue would be found in the same degree in both at the end of 14 days. This demonstrated that skeletal connective tissue (represented by periosteum, endosteum, and connective tissue in the haversian canals) in or about the transplant is of fundamental importance for new bone formation. When natural nourishment is restored to the bone tissue in the fresh pieces of bone, it is able to revive and build new bone tissue just as rapidly as the skeletal connective tissue of the tibia is capable of forming bone.

The subperiosteally implanted, fresh, autoplasmic pieces of bone behave, therefore, in much the same manner as boiled pieces of bone. Boiled and dried pieces of bone, which have been prepared for some time prior to implantation, are replaced by new bone considerably more slowly, and they are probably sometimes not resorbed at all but produce so-called *tole Einheilung*.

In implantation of bone in the skeleton, one should therefore use bone in such form and in

such manner that the skeletal connective tissue in it can quickly revive, and that the living skeletal connective tissue in the compact bone in the bed of the implant may grow into the canal system of the implant as easily and as quickly as possible. To fulfill the first qualification, fresh autoplasmic bone is most ideal; to fulfill the second, bone which I have called "os purum," and which is prepared in a special manner, is nearest ideal.

In the canal system of boiled and dried bone which has been stored for a time, resorption and new bone formation occur considerably more slowly after implantation than in the case of fresh bone or freshly boiled bone, probably because the coagulated and dried up connective tissue, and the collagen converted to glue, must first be resorbed before the connective tissue cells can grow into the canals and react upon the hard calcified material. Such dried bone therefore should not be used for clinical transplantation of bone. In order to obtain material satisfactory from all standpoints, "os purum" has been developed. By means of a physicochemical method of preparation, ordinary bone has been freed as completely as possible of connective tissue, fat, and protein foreign to the host, and the calcified substance made as clean as possible without injuring its mechanical strength. The complicated and time-consuming method of preparation consists chiefly of the removal of the blood proteins by soaking in salt solution, the connective tissue by soaking in warm potassium hydroxide, and the fat by soaking in acetone.

Fresh autoplasmic bone material has long been used as a routine method in surgical transplantation of bone (see especially Olliers, Axhausen, Lexer, and Albee). This method has its limits, however, since such bone transplants are taken from the skeleton of the patient's own body. The bone transplants are therefore limited in size and shape and are

From St. Goran's Hospital, Stockholm, Sweden.
¹Orell, Svante. Studien ueber Knochenimplantation und Knochenneubildung. Implantation von "Os purum" sowie Transplantation von "Os rovim." Acta Chir. Scand., 1934, 74; Suppl. 31.

only slightly variable, and since it is desired also that a portion of the cells survive and take part in the new bone formation, the transplant cannot be handled freely during preparation, but must be treated with the greatest respect.

Barth's theories on this subject dominated the field from 1893 to the time of Axhausen's work in 1908. His theories, based on the microscopic examination of transplants, maintained that the bony substance dies in its entirety and that sterile preserved bone might as well, therefore, be used in bone transplantations. Barth himself used *gegluhter Knochen*, bone which was freed of organic substance by burning. These experiments produced no great progress, probably because in burning the bone, animal charcoal and salts remain in the canals to prevent, or at least to hinder, the ingrowth of living cells from the bed of the transplant. Moreover, the glue resulting from the high degree of heating, becomes insoluble.

Bone fixed in either alcohol or formalin was often used. After fixation it becomes very difficult if not impossible for the cells and the tissue juices in the bed of the implant to resorb the tissues in the implant. Tissues hardened in alcohol or formalin can, as a matter of fact, scarcely be digested even by stomach juices. By boiling and drying the bone, the connective tissue and protein material in the canals are coagulated, as mentioned, and the cells in the bed must first react upon these substances and resorb them before they can reach the bone calcium. This resorption of connective tissue in the canals was first suggested by Marchand in 1900, but had not led to the introduction of any practical measures.

Axhausen (1908), however, was responsible for an entirely different conception. He emphasized the superiority of fresh autoplasic bone transplants, and again as Ollier had previously done, demonstrated the importance of the periosteum in the process of new bone formation after transplantation. Sterilized bone, it is true, has since been used as nails, pegs, screws, bridges, planks, etc., in osteosynthesis, but in transplantations in which the main success of the transplants depended chiefly upon the union of the transplant with the skeleton, fresh bone material

has chiefly been used. As a result of more recent investigations, however, it is perhaps now permissible to carry out certain surgical implantations with the aid of *os purum*, especially since such material offers considerable technical advantages.

I have used the implantation of *os purum* to replace bone which for some reason or other has been resected, most often for tuberculosis. It has been used to fill up the bone defects which result from operation to lessen the chance of producing deformities, and to fix the parts of the skeleton in proper relation to one another in various ways, often after replacing, reshaping or changing the position of them. Many of the patients with implants of *os purum* have now been followed for 4 or 5 years. The wounds have, as a rule, healed without complications, and the implants have shown sufficient strength for their mechanical task until they have gradually been rebuilt and replaced by new bone.

In reporting the following series of cases in which *os purum* has been used, a review will first be made of 3 cases of tuberculous osteitis which were previously described in my thesis. They are included here in order to give the end results at recent follow up examinations. In Case 1 were noted good healing and rebuilding after a resection in which *os purum* was implanted in the diaphysis.

In Case 2 is demonstrated the fact that the implanted *os purum*, just as fresh autoplasic bone is rebuilt to perfectly satisfactory form in spite of the fact that the periosteum of the bed has been damaged through suppuration and excision. In my thesis I have shown, in fact, that after septic osteomyelitis in the metacarpal bones with sequestration and extrusion of the sequestrum, no lasting new bone formation is brought about by implantation of *os purum* after excision of the sear. *Os purum* melts away and is resorbed without leaving any newly formed bone behind.

In Case 3 an osteoplasty of a phalanx of a finger was done and the *os purum* was laid against the freshened defect on the surface of the bone.

CASE 1. V. N. aged 11 years history No. 6 83, 6949 and 7072. Diagnosis tuberculous osteitis of the left first metatarsal. On June 29 1931 a curet

Fig 1 Case 1 Patient had tuberculous osteitis of the first metatarsal at age of 11 years X-ray photographs were taken when patient was 16 years old, 4 years and 8 months after resection and implantation of os purum The small insert shows the condition 48 days after operation The double arrow indicates the site of implantation

tage of the diseased area was done and a homoplastic bone implantation performed after resection of the bone The resected bone was replaced by os purum of similar shape There was primary healing, but about 4 weeks after operation slight swelling and a fistula appeared in the scar, from which clear fluid escaped The fistula dried up after a few days and healed rapidly The plaster cast was removed at the end of 11 weeks Five months after operation the patient was wearing shoes and walking about He was discharged 6 months after operation with a good functional and anatomical result, and went skiing without difficulty a month after coming home He was well at follow-up examinations in 1932, 1933, and 1936 (Fig 1)

CASE 2 H A V, aged 7 years, history No 6841 Diagnosis tuberculous osteitis of the right second metacarpal with sequestration of the metacarpal bone and abscess formation in the soft tissues On December 22, 1931, the bone was resected and a homoplastic bone implantation (os purum) was done The metacarpal was cut through proximally and distally and the interlying bone was removed The abscess in the soft parts was curetted out carefully and cauterized with phenol and alcohol As a substitute for the resected bone, a homoplastic graft of os purum was used After operation, the wound suppurated and broke down and on February 25, 1932, the implant was extracted and the wound cavity revised After the revision, the wound cleaned up quickly and epithelized over On March 16, 1932, implantations of fresh autoplasmic bone and homoplastic os purum were made The os purum (a proximal phalanx) was fitted into the volar half of the metacarpal region The dorsal half was replaced by a transplant taken from the tibia of the patient Healing by first intention occurred The plaster cast

Fig 2 Case 2 Patient had tuberculous osteitis in the second right metacarpal at age of 7 years The x-ray pictures, showing the condition after resection followed by implantation of both os purum and fresh autoplasmic bone from the tibia, were taken when patient was 12 years old Inserts show the bone 69 days after operation

was removed 8 weeks after operation, and the patient was discharged on February 1, 1933 The index finger on the right hand was about 5 millimeters shorter than that on the left The metacarpophalangeal joint showed a range of 45 degrees of flexion and normal extension Follow-up examination in March, 1936, showed a good result with complete replacement of the implant by new bone (Fig. 2)

CASE 3 M H, aged 7 years, history No 6828 Diagnosis tuberculous osteitis of the left second metacarpal with deformity On August 11, 1931, homoplastic os purum (a middle phalanx) was im-

Fig 3 Case 3 Deformity of the middle phalanx of the index finger after healing of tuberculous dactylitis in boy of 7 years a and b, show finger during extension; c, 63 days, d, 610 days, and e, 1601 days after the implantation of os purum into the bone defect producing almost complete restoration of the shape of the finger, patient now 12 years of age.

Fig 4 Case 6 Bone cyst in the right tibia for which curettage and implantation of os purum spongiosum was done Figure shows lateral x rays of the knee left before operation center 169 days after operation and right 711 days after operation Patient 27 years old

planted into the defect in the bone. The wound healed by first intention. The extension wire and plaster cast was removed at the end of 2 months and active motion of the interphalangeal joints begun. The result was good both from a functional standpoint and by x ray, with almost complete restoration of the distal interphalangeal joint and of the shape of the index finger. Follow up examination in March 1936 showed a good result with a complete rebuilding of the implant by new bone (Fig 3).

The rebuilding of os purum may thus be seen to be dependent entirely upon the connective tissue which is present in the bed. If the os purum is implanted beneath the periosteum or next to living bone which contains connective tissue, it is rebuilt without difficulty. If only extraskeletal connective tissue is found in the area around the os purum, the latter is absorbed without being replaced by new bone.

In Case 4 the patient, a 47 year old woman had a tuberculous lesion which was curetted out of the calcaneus and filled with os purum spongiosum. The rebuilding of the implant progressed slowly and was not complete by x ray 720 days after operation, but judging by its clinical appearance, it should have been complete.

CASE 4 I R aged 47 years history No 6709 Diagnosis tuberculous osteitis of the left calcaneus with sequestrum. On August 11 1931 the lesion was curetted out under general anesthesia and os purum spongiosum was implanted. Healing by first intention occurred. On October 21 a superficial ne-

crosis was noted in the scar of the operation on the lateral side of the heel from which clear fluid exuded. Later in November-December, 1931 the wound healed completely. The patient died May 6 1933 of uremia. She was examined the day before death and the heel was then well healed and looked entirely normal.

The 3 following cases illustrate the filling out of defects in the cancellous bone contiguous to the knee joint with os purum spongiosum. Cases 5 and 6 were also reported in my thesis, and are described again here after recent follow up examinations. Case 7 is rather interesting in that the patient had a large abscess extending from the bone lesion into the muscles which was found at the time the implantation was done. The implant began to be rebuilt as soon as the fistula closed and the abscess began to be resorbed.

CASE 5 K V J aged 16 years history No 7050 Diagnosis osteitis fibrosa of the medial condyle of the right tibia. At admission the patient showed general muscular atrophy of the right leg. On the posterior surface of the lateral condyle of the tibia there was considerable tenderness and a somewhat doughy swelling. The motion in the knee joint was fairly good. On May 26 1933 curettage of the lesion was done and os purum spongiosum was implanted. The report of the pathological examination was made by Dr C O Forselius as follows: The microscopic picture may be said to be between that of a fibrosarcoma and a giant cell tumor in any event non malignant. On August 29 1933 he was discharged healed with good motion in the knee joint but with a slight lump on walking. On August 28 1935 he had no complaints and had good motion.

Fig 5 Case 7 Roentgenogram 10 months after curettage of tuberculous lesion and implantation of os purum, in patient 29 years old. The os purum has begun to be replaced by new bone.

CASE 6 H H R, aged 27 years, history No 7105, was admitted to hospital July 15, 1933, with a bone cyst in the medial condyle of the tibia. He had been previously treated in the United States of America. At admission the right knee was fixed in about 45 degrees of flexion and there was marked muscular atrophy of the leg. There was only slight swelling but pronounced tenderness over the medial condyle of the tibia. At operation on July 27, 1933, the tuberculous lesion was curetted out and os purum spongiosum was implanted. The lesion, of lima bean size, contained clear fluid, but no necrotic tissue. It was filled with os purum, and the healthy bone which had been removed was replaced in the bone canal also. Healing by first intention occurred. Seven weeks after operation the patient was allowed to get up without a dressing and was permitted active motion. He was discharged on October 21, 1933, with normal extension and 105 degrees of flexion. On November 12, 1934, he was in good general condition. He had no complaints referable to the knee, and had as good motion in the knee which had been operated on as in the other. There was no muscular atrophy. A certificate of good health was given for his return to the United States. The microscopic report by Dr C O Forselius read as follows: "Bone tissue, partly necrotic, partly forming new bone. The bone marrow is in large part fatty and poor in cells. Here and there a collection of lymphocytes and plasma cells but nowhere a picture typical of osteitis fibrosa" (Fig 4).

CASE 7 V F, aged 29 years, history No 7371. This patient had a tuberculous focus of hazel-nut size in the medial femoral condyle of the right femur with a large abscess in the soft parts. On April 30, 1935, the lesion was removed by operation and os purum spongiosum was implanted. Healing by first intention occurred. Repeated abscesses had to be drained subsequent to the operation. A fistula appeared again on August 17 and 5 to 10 cubic centimeters of thick pus was expressed through it. A progress note on November 24, 1935, stated that no suppuration

Fig. 6 Case 8 Top, 217 days after curettage of tuberculous lesion in the neck of the femur and implantation of os purum in boy of 7 years; center, 301 days later when a similar operation was performed on the acetabulum; bottom, 558 days after the first operation and 311 days after the second operation.

from the fistula had occurred for 14 days. The knee was then non-tender to palpation and there were no signs of abscess formation. The patient lacked 10 degrees of full extension, and the flexion ability lacked 30 degrees. She was out of bed the entire day without complaints. She was discharged on March 8, 1936, in good general condition. The knee was healed and had improved in its mobility. The muscles of the leg were stronger and there was beginning replacement of the os purum by x-ray (Fig 5).

Case 8 showed a tuberculous lesion in the neck of the femur which was curetted out and filled with os purum spongiosum. Half a year later a lesion was discovered in the acetabulum and was similarly treated. The wounds healed well after both operations. The joint space was normal and the function of the joint was good. In Case 9, a walnut-sized lesion in the os pubis was curetted out and filled with os purum with a similar result.

CASE 8. L B O, aged 7 years, history No. 7369. Diagnosis: tuberculous osteitis of the left femoral

neck and acetabulum. On September 18, 1934, the diseased area was removed surgically and os purum spongiosum implanted. In the anterior portion of the junction between the femoral neck and the trochanter granulation tissue was encountered, and a pea sized area of bone necrosis was curetted out and replaced by os purum. Healing by first intention occurred. On May 23, 1935, a diseased focus in the acetabulum was removed by a second operation and os purum spongiosum was implanted. A triangular flap of the outer table of the ilium was raised up with the base toward the edge of the acetabulum. The focus was reached with a curette, cauterized with carbolic alcohol and filled with os purum. First intention healing occurred. On May 3, 1936, the patient was in good general condition. The gait and motion in the hip joint was good (Fig. 6).

CASE 9. E. M. K. aged 4 years, history No. 7424. Diagnosis: tuberculous osteitis in the right os pubis with a walnut sized lesion in the superior ramus of the os pubis. At operation on April 4, 1935, the diseased area was removed and os purum spongiosum was implanted under ether anesthesia. The anterior wall of the symphyseal cartilage was intact. It was broken through carefully with a chisel where upon a cavity was encountered filled with necrotic and partially caseous masses. These were removed. The cavity had a very irregular shape but was filled up as well as possible with os purum. Healing by first intention occurred. On May 3, 1935, the patient was in good general condition. Rebuilding of the os purum had taken place to a considerable degree according to x rays but was not yet fully complete.

Cases 10, 11 and 12 exhibited tuberculous lesions with involvement of the neighboring joints in one or more tarsal bones. These lesions were curetted out and filled with os purum. In all these cases, healing was by first intention and the subsequent function was good. Of these cases, Case 10 has been followed 483 days and the rebuilding has been good. Case 12 has been followed 1½ years.

CASE 10. W. G. S. aged 24 years, history No. 7236. Diagnosis: tuberculosis of the right tarsus. Neither tenderness nor swelling over the talocalcaneal joint was very great although the patient complained of pains in the heel upon walking. There was some limitation of dorsal flexion of the foot. The right calf measured 3 centimeters less in circumference than the left. At operation on May 12, 1934, the lesion was found lying immediately against the talocalcaneal joint and was curetted out and replaced with os purum spongiosum under spinal anesthesia. The pathological report was tuberculosis. The wound healed by first intention and the patient was discharged on July 5, 1934, free of complaints. On September 7, 1935, he still was without complaints and had good motion in the foot.

CASE 11. J. P. J. aged 64 years, history No. 7355. On the medial border of the right foot there was an ulcer about 1 centimeter long at the anterior border of the os naviculare with low grade suppuration. There was no swelling of the soft parts. There was tenderness to palpation on the dorsum of the foot over the os naviculare. At operation on November 17, 1934, under local anesthesia, a small cavity containing granulations was encountered which extended forward toward the joint between the os naviculare and the first os cuneiforme. The lesion together with the neighboring bone and portions of the cartilage were curetted out and replaced with os purum. The wound healed by first intention and the patient was discharged on February 21, 1935, with a good anatomical and functional result.

CASE 12. A. E. N. aged 25 years, history No. 7191. Diagnosis: tuberculosis of the tarsus with multiple osteitis. For about 2 months there had been tenderness upon palpation of the dorsum of the right foot especially immediately anterior to the head of the talus. By x ray osteoporosis of the metatarsal bones was apparent and the joint cartilage of the small joints of the right foot did not show as clearly as those of the left foot. Curettage of the bone lesion was performed on November 30, 1930, under spinal anesthesia. The joint capsule between the os cuboideum and the third os cuneiforme showed pathological changes and was excised. In two neighboring portions of the bone tissue showing tuberculous changes was curetted away. The portions curetted out were replaced by os purum spongiosum. The wound healed by first intention. At follow up examination on May 3, 1936, the result was good both functionally and by x ray.

In Cases 13 to 17, tuberculous lesions of the bone at the wrist, with involvement of the neighboring joints, were curetted out. In 3 of the cases (13, 15, and 17) the healing and rebuilding has been exceptionally good. Two of the cases which had large abscesses and fistulas before operation had postoperative complications. Case 14, a flaring up of pulmonary tuberculosis (patient referred to a sanatorium). Case 16, an old woman, a pulmonary embolus 5 months after operation causing sudden death.

CASE 13. E. E. aged 24 years, history No. 7101. Diagnosis: tuberculous arthritis of the right radio carpal joint with abscess formation and threatening perforation of the skin. At operation on August 1, 1933, the bone lesions in the os naviculare, os lunatum and radius were curetted out under brachial plexus block anesthesia and os purum was implanted. The wound healed by first intention. However, in the third week after operation a few drops of clear fluid appeared through a small fistula in the scar but subsequently remained dry. Three months

TABLE I—IMPLANTATION OF OS PURUM IN RESECTIONS OF THE ANKLE JOINT FOR TUBERCULOSIS

Case No	History No	Patient's initials	Age	Sex	Resection		Healing	Walked without cast most postoperative	Rebuilding of implant—days after operation	Form of foot	Remarks

E=Ether anesthesia, S=Spinal anesthesia

after operation the plaster cast was dispensed with and free use was permitted. The functional and anatomical result was good and there was no collapse of the os purum. A fair amount of motion returned in the wrist joint. Patient has been re-examined every 6 months.

CASE 14. E I E A, aged 30 years, history No 7047. Diagnosis: tuberculosis of the wrist joint with abscess formation and threatening perforation of the skin. A resection of the wrist joint was performed on August 1, 1933, under ether anesthesia. The resected bone was replaced by a layer of os purum spongiosum. Healing was complicated by the appearance of a fistula which soon dried up. The patient was referred to a sanatorium for pulmonary tuberculosis 6 months after operation, where she died a few months later.

CASE 15. B A O., aged 26 years, history No 7366. Diagnosis: tuberculosis of the left wrist joint with multiple areas of osteitis. There had been increasing diffuse swelling of the left wrist with the formation of a fluctuant abscess on the dorsal aspect. Curettage of the bone lesion and implantation of os purum spongiosum was done on October 10, 1934. The joint capsules were excised and replaced with os purum. Healing appeared to be by first intention, but about 2 months after operation there was some serous discharge through a small fistula in the scar. A small abscess appeared in the skin and was incised. After this procedure was carried out prompt healing followed.

CASE 16. Age 68 years. History No 7399. Diagnosis: tuberculosis of the wrist with abscess formation and threatening perforation. Perforation occurred on December 29, 1934. At operation on January 3, 1935, a large tuberculous lesion was curetted out of the wrist bones and the radius and was replaced by os purum spongiosum, under brachial plexus block anesthesia. Healing was complicated by suppuration through a fistula. The patient died suddenly of a pulmonary embolus on May 7, 1935. No postoperative x-ray pictures had been taken before death occurred.

CASE 17. A E P, aged 29 years, history No 7421. Diagnosis: tuberculosis of the right wrist. There was marked swelling and destruction of the end of the radius and the proximal carpal bones at admission. Curettage of the lesion was done on June 7, 1935, and the removed bone was replaced by implantation of os purum spongiosum under brachial plexus anesthesia. The wound healed by first intention. The plaster cast was dispensed with after about 2 months. The patient was discharged on September 13, with the wound well healed. The hand was in good position and had good contour, without collapse of the area. There was only a couple degrees of motion in the wrist joint, but there was good motion in the finger joints. At follow-up examination on February 3, 1936, the mobility and strength had increased. The result was good, both from a functional standpoint and by x-ray.

Table I gives data regarding 8 cases (Cases 18 to 25) of tuberculosis of the ankle joint in which resection was performed and the resected bone was replaced by a piece of os purum spongiosum with the aim to preserve the shape of the foot as much as possible. In all except Case 24, in which a fistula was present before operation, healing was by first intention. The strength and rebuilding of the implants, and also the shape of the foot, have all been good.

CASE 18. E I K., aged 17 years, history No 6633, 6956, 7073, 7363, and 7586. The patient had an old tuberculosis of the right talocrural joint which had flared up several times. A trial of conservative treatment was first made, but swelling, tenderness on pressure, and pains about the joint persisted. On September 9, 1931, a resection of the ankle joint was done and the resected bone was replaced by implantation of homoplastic os purum spongiosum. The wound healed by first intention, and the pa-

Figs 7 and 8 Case 18 Figure 7 was taken 57 days after resection of the ankle joint and insertion of os purum for

tuberculosis in a patient 17 years of age Figure 8 was taken 4 years after operation

tient was out of bed walking in a cast 3 months after operation. There was functional and anatomical healing without collapse of the os purum (Figs 7 and 8). Follow up examination in August, 1935 showed the foot to be in good position with 5 to 10 degrees of equinus. The range of motion for plantar and dorsal flexion was 15 to 20 degrees. A few degrees of pronation and supination were present. There was no pain on motion and general strength was satisfactory. The calf musculature of the right leg was somewhat atrophied. He could walk remarkably well and could run easily and without difficulty. The patient worked in a lumber yard carrying planks and lumber without trouble.

CASE 19 K. M. A. aged 9 years history No 6573 69.55 The patient was admitted to the hospital with signs of an acute process in an area of old tuberculosis in the right talocrural joint. The patient was treated conservatively at first but because of angu-

lation of the foot resection of the joint was decided upon. This was performed on September 9 1931 and the resected bone was replaced with a piece of os purum spongiosum. The wound healed by first intention and the patient was up and walking with a plaster cast 2½ months after operation. The functional and anatomical result was good without collapse of the os purum. The patient was discharged on April 22 1932. Follow up examination on August 10 1932 showed the foot to be well healed and ankylosed in good position.

CASE 20 B. F. aged 20 years history No 6838 Since the end of 1920 the patient had had symptoms from tuberculosis of the talocrural joint sometimes improving then becoming worse again. There had been abscess formation of late. On April 6 1932 resection of the joint was performed and the resected bone was replaced with a layer of os purum spongiosum. On June 9 the patient was out of bed walking with a plaster cast and was discharged on September 30 with a leather support which he wore until January 15 1933. He then walked well without it. Three years after operation on July 14 1935 his general condition was good. The sedimentation rate was 4 millimeters in an hour. The position of the foot was good and there was no difficulty in walking even when the gait was rapid. There was about 5 degrees of motion in the ankle joint. There was no impairment of motion in the toes or knee and he had no pain or tenderness. He has now learned the tailoring trade having been a textile worker prior to his illness.

CASE 21 S. C. S. aged 16 years History No 6877 The patient entered with an exacerbation of old tuberculosis of the left talocrural joint. Since her fistulas had closed on September 1 1932 a resection of the joint was done October 6 1932 and the resected bone was replaced with os purum spongiosum. First intention healing was obtained. The patient walked without her plaster cast in the fourth month after operation. There was good functional and anatomical healing without collapse of the os purum. She was discharged on March 19 1933 with

Fig 9 Case 26 Tuberculosis of the knee joint in patient aged 37 years. Anteroposterior and lateral roentgenograms 4½ years after resection of the joint and implantation of os purum spongiosum together with a tongue of os purum compactum.

Fig 10 Case 39 Tuberculosis of knee joint in a patient 21 years old Anteroposterior and lateral views 193 days after resection of the joint and implantation of a tongue of os purum compactum

the wound well healed and with good motion in the joints of the foot. The cast was dispensed with on March 10, 1935. Follow-up examination 2½ years after operation showed good general condition. The patient walked well without a limp, but she experienced occasional ache in the joints of the foot with change in weather. She works at home.

CASE 22 T I P, aged 25 years, history No 7005. Diagnosis tuberculosis of the left talocrural joint. The patient had had trouble with the left foot since the beginning of 1932. An operation was decided upon, since the trouble did not disappear in spite of bed care and fixation in plaster. A resection of the joint was done on May 11, 1933, and the resected bone was replaced with os purum spongiosum. Healing was by first intention. The plaster cast was removed 2 months after operation, and 4 months after operation the patient was able to walk without a supporting bandage. There was good functional and anatomical healing without collapse of the os purum, but there was some valgus position of the foot because the os purum had not been correctly shaped. At follow-up examination on June 12, 1934, the general condition was good. The valgus position was still present. There was 10 degrees of motion in the ankle joint. She had worked at home house-keeping for the last 7 months without trouble.

CASE 23 I L, aged 13 years, history No 7151. The patient was admitted to the hospital August 28, 1933, with a diagnosis of tuberculosis of the left talocrural joint. For 4 weeks a latent tuberculosis of this joint had been flaring up. Operation was decided upon because of threatening perforation of secondary abscesses. A resection of the joint was performed on November 30, 1933, and os purum was inserted to replace the resected bone. Healing was by first intention and the patient was out of bed walking without a cast on March 1, 1934. He was

Fig 11 Case 37 Tuberculosis of the knee joint with atrophic and friable cancellous bone in patient 27 years old. Roentgenogram shows condition 111 days after resection of the joint and implantation of a thick plate of os purum spongiosum.

discharged on May 14, 1934, with some atrophy of the musculature of the left thigh and calf. He had then been up and about for a month and could walk well. The foot had good shape and good function. On August 17, 1935, the general condition was good, and the gait was satisfactory. The foot looked well, still had good shape, and did not swell. The sedimentation rate was 25 millimeters. The patient was taking part in all kinds of sport.

CASE 24 A E F, aged 49 years, history No. 7280. Diagnosis tuberculosis of the right talocrural joint with fistula formation. The patient had had aches

Fig 12 Case 47 Tuberculosis of the shoulder joint in a woman 52 years of age. Roentgenogram shows the condition 328 days after shoulder joint resection with implantation of os purum in a large defect in the cancellous portion of the head of the humerus.

Figs 7 and 8 Case 18 Figure 7 was taken 57 days after resection of the ankle joint and insertion of os purum for

tuberculosis in a patient 17 years of age Figure 8 was taken 4 years after operation

tient was out of bed walking in a cast 3 months after operation. There was functional and anatomical healing without collapse of the os purum (Figs 7 and 8). Follow up examination in August, 1935 showed the foot to be in good position with 5 to 10 degrees of equinus. The range of motion for plantar and dorsal flexion was 15 to 20 degrees. A few degrees of pronation and supination were present. There was no pain on motion and general strength was satisfactory. The calf musculature of the right leg was somewhat atrophied. He could walk remarkably well and could run easily and without difficulty. The patient worked in a lumber yard carrying planks and lumber without trouble.

CASE 19 K M A aged 9 years history No 6573 6955. The patient was admitted to the hospital with signs of an acute process in an area of old tuberculosis in the right talocrural joint. The patient was treated conservatively at first but because of angu-

lation of the foot, resection of the joint was decided upon. This was performed on September 9 1931 and the resected bone was replaced with a piece of os purum spongiosum. The wound healed by first intention and the patient was up and walking with a plaster cast 2 1/2 months after operation. The functional and anatomical result was good without collapse of the os purum. The patient was discharged on April 2, 1932. Follow up examination on August 10 1932 showed the foot to be well healed and ankylosed in good position.

CASE 20 B E aged 20 years, history No 6838. Since the end of 1929 the patient had had symptoms from tuberculosis of the talocrural joint sometimes improving then becoming worse again. There had been abscess formation of late. On April 6 1932 resection of the joint was performed and the resected bone was replaced with a layer of os purum spongiosum. On June 9 the patient was out of bed walking with a plaster cast and was discharged on September 30 with a leather support which he wore until January 15 1933. He then walked well without it. Three years after operation on July 14 1935 his general condition was good. The sedimentation rate was 4 millimeters in an hour. The position of the foot was good and there was no difficulty in walking even when the gait was rapid. There was about 5 degrees of motion in the ankle joint. There was no impairment of motion in the toes or knee and he had no pain or tenderness. He has now learned the tailoring trade having been a textile worker prior to his illness.

CASE 21 S C S aged 16 years History No 6877. The patient entered with an exacerbation of old tuberculosis of the left talocrural joint. Since her fistulas had closed on September 1 1932 a resection of the joint was done October 6 1932 and the resected bone was replaced with os purum spongiosum. First intention healing was obtained. The patient walked without her plaster cast in the fourth month after operation. There was good functional and anatomical healing without collapse of the os purum. She was discharged on March 19 1933 with

with such an osteosynthesis, and the plaster cast may be taken off as early as 6 months after operation. The expense of a leather support is eliminated by these measures

Judging from the x-ray pictures, it takes about 1 year before the bony structures in the tibia and femur begin to grow over into one another. In the anteroposterior views, the tongue of bone is well outlined until about 400 days after operation; subsequently it is difficult to make out. In the lateral views, however, the tongue of bone may be seen to be more dense than the surrounding bone as late as 4 years after operation. Compact os purum is rebuilt very slowly (see Figs 9, 10, and 11).

In Table III, 5 cases of shoulder joint tuberculosis which have been treated by resection are described (Cases 44 to 58). At operation, the defects in the resected ends have been replaced with os purum spongiosum and the end of the humerus held in position by means of a

tongue of bone driven into the anterior margin of the glenoid labrum. Healing has invariably been by first intention and union has been good. The rebuilding of the implant has also been good. In these cases evipan and ether anesthesia have been used in combination, with great advantage. Since the cases have not been followed more than 1 year, the rebuilding of the implants is not yet complete.

CASE 44. E G K, female, aged 18 years, history No 7289. Diagnosis: tuberculosis of the right shoulder joint. The patient had had pain, tenderness, and increasing stiffness in the right shoulder joint, since 1931. On March 29, 1933, a resection of the shoulder joint was done under ether anesthesia. The head contained extensive necrotic areas which were cleaned out. The posterior portion of the capsule of the shoulder joint contained a great deal of granulation tissue and caseous material. A secondary abscess had formed in the axilla. All the diseased tissue was removed. The cartilage of the glenoid cavity was necrotic with caseous areas beneath. These were curetted out also. When the head of the humerus and the glenoid cavity were smoothed off, they did

Fig 14

and swelling in the right foot since the beginning of 1934. At admission on May 15 1934 there was on the right foot just lateral to the malleolus a fistula about 1 centimeter in diameter and with considerable discharge. The fistula had soft granulations in its depths and the skin immediately surrounding it was bluish red in color. The underlying tissues were somewhat swollen. Motion of the ankle joint was especially painful upon flexion. On January 15 1935 there was only a slight amount of secretion from the two fistulas. A resection of the ankle joint was performed on January 17 1935. Many masses of tuberculous granulations were found in the capsule and on the surface of the joint. The joint cartilage was missing. The granulations were removed and the surface of the joints was scraped clean and smoothed off, after which a layer of os purum spongiosum about 1 centimeter thick was placed between the surfaces of the resected area. On July 13 the patient was permitted to walk with a plaster cast and on December 27 it was dispensed with. At follow up examination on January 29 1936 it was learned that there had at times been some serious discharge through a small fistula since operation. X-ray examination revealed that the implant had maintained itself well but had not yet begun to be rebuilt.

CASE 25 B C F C aged 17 years history No 7359 7394. Diagnosis tuberculosis of the left talocrural joint. The patient was admitted to the hospital on August 17 1934. There had been swelling of the foot since March 1934. A resection of the

joint was done on January 26 1935. The resected bone was replaced with a layer of os purum spongiosum and healing by first intention was obtained. The plaster cast was removed April 8. The patient walked without support on April 24 and was discharged June 6 1935 without complaints and with a well healed wound.

In Table II 18 cases (Cases No 76 to 43) of knee joint tuberculosis treated by resection are outlined. I have not included the full case histories for lack of space. The implantation of os purum in these cases is only one step in a resection which is often quite complicated and meticulous in its performance.

At resection the defects in the resected surfaces were replaced with os purum spongiosum and the resected ends were united by osteosynthesis by driving in a strong tongue of os purum compactum through the anterior portions of the tibia and femur in the frontal plane. The latter procedure is an advantageous technical detail in the operation. After the tongue of bone has been driven in, it is considerably easier to put on the plaster cast with the leg in good position than if only sutures are used. More important however is the fact that bony union becomes firm earlier.

E=Ether, Ev-E=Evipan-Ether, B=Tongue of os purum; D=Defect in bone substance replaced by os purum

CASE 49 E B, aged 13 years, history No 6846
Diagnosis genu varum following tuberculous coxitis. On March 18, 1933 an infracondylar osteotomy of the tibia was done and os purum was implanted. After the usual incision in the soft parts, the operation was carried out with drill and osteotome. With retractors the ends of the bone were forced apart, and small pieces of os purum were interposed between the medial ends of the bones so that the proper relationship between them existed. The periosteum and the overlying soft parts were sutured. A fenestrated circular plaster cast was placed about the leg and foot. Healing was by first intention. At the end of 8 weeks, the patient was up and walking with the plaster cast on. Figure 13 shows the x-ray pictures the day after operation, 202 days after operation, and 455 days after operation. The patient was discharged on January 17, 1934, with complete ankylosis in the left hip joint and with the lower leg in good position. She limped slightly but otherwise walked quite well.

Implantation of os purum has given healing by first intention as a general rule. During the third or even the seventh week after implantation, a fistula has sometimes appeared in the scar and serous fluid broken out through it, probably due to tissue necrosis. The discharge has usually ceased after 1 or 2 weeks, and the wound has subsequently remained dry. The portion of the body operated upon has in general been immobilized in a plaster cast for 2 or 3 months after the implantation, and the cast has been fenestrated over the wound so that the latter could be observed carefully. The wound has been covered with a bandage only during the first few days after operation and afterward left exposed to the beneficial effects of sunlight and ventilation.

According to the results of my own investigations, implantation of os purum should be

preferably done in cases of bone tuberculosis when the disease is in a quiescent stage and when the lesions have shown some tendency toward localization. Even in many cases of joint resection in more active forms of tuberculosis, however, os purum may give a good result. It is only in cases in which fistulas have formed, or in cases in which the overlying skin has been rendered thin and unhealthy by secondary infection or abscess formation that the implant is sometimes extruded. Considerable space would be required to review in detail the indications for operation, at least so far as surgical tuberculosis is concerned. These can be learned only through practical experience in the clinic where one may see for himself and follow the treatment and course of healing among the cases.

When one wishes to learn the technique of the use of os purum for implantations, he should begin with simple procedures. Later, after a survey of the results of these cases, he should pass on to more difficult problems. In this way uncertainty is eliminated and increasing trust in the use of os purum is acquired.

In using os purum, an especially careful aseptic technique is demanded, together with a few specially constructed simple instruments which have been described in previous communications.^{1,2} Besides these instruments, it is advantageous to have wooden tampons (Fig. 14) for the introduction of the os purum into its bed. Sterilization of os purum is most easily accomplished by boiling in physiological

¹Orell, Svante. Osteoplastic cuneiform osteotomy in the treatment of ankylosis. *J. Bone & Joint Surg.*, 1932, 14, 613.

not fit each other well the head tended to luxate anteriorly. A tongue of os purum was therefore driven into the anterior portion of the glenoid rim in order to hold the head in place. Good position then seemed to be maintained. On April 29 1936 the general condition was good. The patient stated that she occasionally had pain in the region of the scapula, probably originating in the musculature. The shoulder joint was ankylosed with the upper arm held at an angle of 60 to 70 degrees with the lateral edge of the scapula.

CASE 45 O K male, 31 years of age, history No 7395. Diagnosis tuberculosis of the left shoulder joint. The patient had been well until the autumn of 1933, when he first noticed a swelling in the left supraclavicular fossa. This swelling produced no subjective discomfort, but increased gradually in size. In May 1934 it was of hen's egg size. On February 12, 1935 the shoulder joint was resected under ether anesthesia. The head of the humerus contained a sequestrum the size of a walnut, which was removed. The joint capsule was also removed. The glenoid cavity was cleaned out with a curette, and a tongue of os purum was driven into the anterior edge against which the smoothed off head of the humerus rested so that it was held in good position. A fenestrated circular plaster bandage was placed about the thorax upper arm and forearm. The wound healed by first intention and the patient was discharged May 25 1935, wearing the plaster cast. He has returned for observation every 3 months. On April 6 1936 the general condition was good and the plaster was removed. There was ankylosis of the shoulder joint. Remnants of the tongue of bone were still visible in the x ray pictures.

CASE 46 T A male aged 29 years history No 7435. Diagnosis tuberculosis of the right shoulder joint. Since July 1934 the patient had had continual trouble with increasing stiffness in the right shoulder joint. On April 5, 1935, the shoulder joint was resected under evipan ether anesthesia. The cartilage on the humeral head was necrotic and was loosened over its greater part. Several pea sized tuberculous areas in the head were curetted out and cleared of granulations. The entire capsule was carefully removed. The glenoid cavity was curetted free of necrotic cartilage granulations and caseous material. In the lower portion of the glenoid cavity a funnel shaped cavity was encountered having a base about 1 centimeter in diameter. This was also curetted out. The entire field of operation was cauterized with carbolic acid and alcohol and the defect in the glenoid cavity was filled with os purum spongiosum. The head was easily fitted into the glenoid cavity and fixed in 90 degrees of abduction 20 degrees of forward flexion and 20 degrees of internal rotation. A fenestrated circular plaster was made to include the thorax the upper arm and forearm. Healing was by first intention and the patient was discharged on June 5 wearing the plaster cast. He returned every 3 months for observation. On February 5 1936 the shoulder joint looked fine and

had good stability. The scar was well healed. There was good motion in the elbow and hand and the strength was good. X ray picture showed that healing and consolidation were taking place.

CASE 47 A P, aged 52 years history No 739. Diagnosis tuberculosis of the right shoulder joint. The patient had had ache soreness, and stiffness in the right shoulder joint since 1930 and had recently had a secondary abscess. The joint was resected on March 4 1935. In the center of the head of the humerus, a large caseous necrosis was found. This was curetted out and filled with os purum spongiosum. Healing occurred by first intention and the patient was discharged on August 24, 1935 with the arm in a leather support. On January 26 1936, the joint was well healed with the arm in good position. The joint has since become ankylosed (Fig. 12).

CASE 48 T B male aged 45 years history No 7425. Diagnosis tuberculosis of the right shoulder joint. The patient had had trouble with the right shoulder joint since childhood. During the last 2 years he had had increasing aches and pains in it together with diminution in the mobility of the joint. The patient consented to operation and on March 13 1935 a shoulder joint resection was done under evipan ether anesthesia. The head was found to be luxated and was replaced. The joint capsule was excised and the wound cavity cauterized with carbolic acid and alcohol. Because of the marked adduction contracture the head was smoothed off, whereupon lesions were found within it. One bean sized area extended down into the neck of the humerus. These were curetted out and filled with os purum spongiosum. In order to hold the head in the glenoid cavity, a tongue of os purum was driven into the antero-superior portion of the glenoid rim. A fenestrated circular plaster cast was made to include the thorax upper arm and forearm. Healing was by first intention and the patient was discharged on May 24 with a shoulder cast. On April 10 1936 the general condition was good. There was bony union by x ray examination. The patient had removed the cast 14 days previously. He was engaged in slow work and played the piano and violin without difficulty.

Case 49 is one of interposition osteosynthesis of the tibia for genu varum following tuberculous coxitis. In the same manner that a bone fragment can prevent reposition in a comminuted fracture and fix the ends of the bone in a faulty position, so through the use of interposition in an osteotomy, bone or joint resection, fracture, etc. reposition and fixation of the ends of the bone in the desired position may be obtained. This is especially important in osteotomies etc. in which fixation after reposition often cannot be done at all or with great difficulty solely by means of external appliances.

DIABETES AND PREGNANCY

W. W. HERRICK, M.D., and ALVIN J. B. TILLMAN, M.D., New York, New York

IT IS now more than a decade since the use of insulin in the diabetes of pregnancy became general. A sufficient time has therefore elapsed for the collection of material upon which to base reliable estimates of its effectiveness. Among the many contributions to the subject in the literature, the most notable are those of Skipper, White, and Peckham. A body of opinion has been built up by these and other studies which may be given a brief review.

The disease may antedate or arise in pregnancy; it may be either mild or severe, and either badly or well controlled by treatment. Unquestionably, severe diabetes affects the reproductive function adversely. Menstrual irregularities or amenorrhea are almost the rule in severe diabetes, as are undernourishment and retarded development. The effect of this in reducing activity of the pituitary, thyroid, and reproductive glands is well known. A lack of estrin, a disappearance of graafian follicles and lack of genital development are described. It is the common experience that these deficiencies may be overcome by proper insulin treatment, and one result of such treatment is the greater fecundity of the victim of severe diabetes, a fact which complicates the problem of management during gestation and labor.

Diabetes with onset during pregnancy presents diagnostic problems for a number of reasons. The metabolic equilibrium of pregnancy is relatively unstable. In addition to the disordered carbohydrate metabolism there is an increased metabolic rate averaging 14 per cent in the last trimester, a diminished alkali reserve, a tendency to acidosis, a lowered plasma combining power of the blood for carbon dioxide, and a tendency to depletion of the glycogen store with resulting hypoglycemia. A lowered renal threshold for glucose is common in pregnancy, often associated

with a lowered assimilation limit for carbohydrate. Even in the non-diabetic pregnant woman the blood sugar curve after the administration of 100 grams of glucose may approach or assume the "plateau" or diabetic form. In most cases these metabolic changes are temporary; in a few they mark the onset of diabetes. Often only after careful and repeated study of the sugar in the blood and urine is it possible to determine whether or not a given pregnant patient with glycosuria is really diabetic, and on occasion a follow-up study in the postpartum period may be necessary.

The requirements of the fetus create a demand for about 50 grams of additional carbohydrate each 24 hours in the later months of pregnancy. The possibility that the fetal pancreas and other glands of internal secretion supplement corresponding maternal mechanisms is not yet definitely proved. This may well introduce a further factor making for a disturbed physiological equilibrium.

As regards the infant, diabetes in pregnancy is almost if not quite as menacing as in the pre-insulin era. The fetal and infant mortality remains little changed and seems to vary directly with the severity of the maternal diabetes and the effectiveness of its control. An opinion widely expressed states that the children of diabetic mothers weigh at birth much more than the average. This has been said to lead to prolonged labors with attendant possibility of fetal or maternal injury. The explanation for this increase of fetal size is not clear, and the anomaly is said not to have varied since the administration of insulin. Theoretical speculations assign it to super-alimentation, the consequence of maternal hyperglycemia or lipemia, to hyperplasia of the fetal islands of Langerhans, or to anomalous endocrine influences. That the increase is due largely to skeletal development and to fat brings up the question of the possible implication of the pituitary. The recent findings of Smith of a prolactin-estrogen imbalance in

sodium chloride solution, this, in addition, slightly softens the collagen in the os purum and perhaps makes it more easily soluble by the cells and tissue juices in the tissue bed. Since the os purum becomes somewhat soft in consistency after sterilization, wooden instruments spare the soft spongy framework more than hard steel instruments.

It must be remembered, in the use of os purum, that a good clinical result from its implantation may be expected only when skeletal connective tissue is present in the bed of implantation. Thus, in implants into the epiphysis large surfaces of cancellous bone must lie against the os purum, and in implants into the diaphysis, living periosteum as well as compact bone must surround it.

SUMMARY

In bone implantations, either fresh bone which contains connective tissue may be used, or a specially prepared bone introduced by the author and called "os purum," or the two may be used together. Cooked bone which has been dried, or bone which has been fixed in fixing solutions is not suitable for implantations. The use of os purum has the following advantages:

1. Since fresh autoplasmic bone contains living bone connective tissue, it must be treated with great respect at implantation. Os purum, however, can be handled with much greater freedom and may be shaped in any

manner best adapted to the situation provided it is sterile when placed in the tissues.

2. Os purum may be stored and kept over a considerable period of time, and a number of sizes and shapes may be prepared by machine beforehand. The form best suited for the portion of the skeleton which is to be repaired or reshaped may then be selected from among them.

3. No limitations as to size and shape are imposed, as is true when fresh bone is taken from the patient's own skeleton.

4. By using os purum in bone implantations, the accessory operation to obtain fresh autoplasmic material is rendered unnecessary. The operative procedure is thereby shortened and simplified, and the risk for the patient is consequently lessened.

5. By implantation of os purum together with fresh autoplasmic material, the more difficultly obtained material may be spared and good shape and filling still be attained in the injured or deformed skeletal part by the supplementary use of os purum.

A series of cases of tuberculous osteitis and osteoarthritis is reported, together with a case each of bone cyst and osteitis fibrosa, in the operative treatment of which, os purum has been implanted in various ways. In the cases os purum has healed in, as a rule, without complication and has had sufficient stability for its mechanical task until it has been gradually rebuilt and replaced by new bone.

TABLE III.—PREVIOUS OBSTETRICAL HISTORY

The gravidity of these patients when first observed at the Sloane Hospital and the number of living children at the time are shown in Tables IV and V. Seven of the childless patients were multiparas, the others, primiparas.

Table VI, giving height and weight, shows a tendency to shortness of stature in these diabetic women. There is not, however, a conspicuous preponderance of obesity.

COURSE AND MANAGEMENT

The antepartum complications in this series are of striking interest. Especially noteworthy is the great liability to late toxemia. In the 12 who evidenced a complicating toxemia, the blood pressure ranged from 150 to 180 millimeters mercury systolic, and 90 to 120 millimeters mercury diastolic, the average being 166 millimeters mercury systolic and 105 millimeters mercury diastolic. Albuminuria was either absent altogether or rose to 8 per cent

before delivery. This striking association of diabetes in pregnancy with the vascular type of toxemia may have peculiar significance which will be discussed in a further paragraph. Other antepartum complications seem less important and are relatively infrequent.

The management of this group of diabetic pregnant women was not consistent. Some were private patients who were admitted for delivery only and had, therefore, incomplete hospital records. Others were emergency admissions for delivery only. There was a group of unco-operative patients whose care had

TABLE I—OUTCOME OF PREGNANCIES

toxemias of pregnancy and in those pregnant diabetics who developed toxemia or who had either stillbirths or edematous giant infants adds further support to these theories

The greatly increased liability to intra uterine death is typical of diabetes. The cause is not yet known. It may be associated with the vascular type of toxemia with hypertension, with hydramnios, or possibly with disturbed function of the endocrine glands concerned in reproduction. Hyperglycemia and ketosis definitely promote fetal death. Maternal hypoglycemia as a cause of fetal death seems unlikely. Skipper states that a moderate fetal hypoglycemia is frequent in diabetes.

The fetus is often macerated. No characteristic changes in the placenta have been described. Fetal anomalies are said to be much more common in diabetes, among these being monsters, congenital heart lesions, meningocele, mongolian idiots and gastro intestinal atresia. We observed none of these in our series.

The question of the inheritance of diabetes is not yet settled. According to Joslin and associates, the disease tends to be transmitted as a recessive mendelian trait. More than one parent or hereditary carrier must therefore be concerned in its transmission.

PERSONAL OBSERVATIONS

As an addition to the body of the statistical and other studies on the subject we present the experience of a large obstetrical clinic in the management of diabetes in pregnancy within the insulin era. During the first 14 years of this era, 56 patients with diabetes mellitus were observed in 67 pregnancies at the Sloane Hospital for Women. Of these, 40 patients were ward with 46 pregnancies, and 16 were private with 21 pregnancies. The outcome of the pregnancies is shown in Table I.

	5

Among the diabetics in the Sloane Hospital the percentage of stillbirths from all causes was 28.0, this is in contrast with the percentage of stillbirths in all deliveries, which was 4.2.

Family history. The familial tendency to diabetes is well shown in the following tables. It will be noted that of 17 patients in whom a family history is known, 10 gave a history of familial incidence of diabetes: 3 in the father, 1 in a paternal uncle, and 6 in the mother. In addition to diabetes, 1 parent in 2 cases suffered amputation of a foot. Cardiovascular disease was strikingly frequent. The incidence might be even higher as a number of patients were entirely ignorant of their family history.

Personal history. The personal history does not suggest that infection is an important factor in the etiology of this group of cases. On the other hand, it is of interest that there were 5 cases of hyperthyroidism. The age range of onset of the diabetes was from 15 to 38 years, in 11 the age of onset being unknown and not determinable. It is a striking and perhaps exceptional observation that in none of these cases did the diabetes start before puberty. In 11 the diabetes definitely started in pregnancy.

The previous obstetrical history showed that an extraordinary number of these women had stillbirths, miscarriages, or infants that died immediately after birth. Of the 56 patients 17 experienced 86 pregnancies in all, and of these 49, or 57.0 per cent, terminated in stillbirth, neonatal death or abortion. An increased liability to toxemia also revealed by their history.

the determination of the sugar and the carbon dioxide combining power of the blood. Until the vomiting is under control, no attempt is made to supply protein or fat excepting such as may be present with the administered carbohydrate.

The next step in management is the building up of a more normal diet in which the number of calories per kilogram varies inversely with the weight of the patient. The adverse effect of obesity upon diabetes must be regarded. Furthermore, the overweight patient has the added risk of toxemia of pregnancy and in our experience an increased fetal mortality. In the obese, no measure seems to us of more importance in reducing maternal morbidity and fetal mortality than loss of weight during gestation. Even in the undernourished patient an attempt is made to limit the gain of weight during pregnancy to 25 pounds.

In the second trimester, once regulation has been established, there is generally little change in the basic requirements of diet and insulin. In 3 of our patients, however, tolerance decreased, and quite abruptly. This emphasizes the importance of a strict watch over the patient in this period, at intervals of not more than 7 to 10 days.

Between the sixth and ninth months marked changes in tolerance are to be expected. These vary in degree and in time of appearance with the individual patient. For this we lack an adequate explanation. In our series the charts of 20 patients gave data sufficient to permit evaluation of tolerance. In 9 of these there was very definite improvement as term approached, but in 7 there was just as marked a decrease in tolerance. This fact is very important in therapy. Only 4 of our patients showed an apparently unchanged tolerance throughout pregnancy. Decline in tolerance over a short period of time, if not promptly treated, may result in destruction of the fetus. It is important to remember that normal laboratory findings are not a guarantee that the diabetes will remain under control.

With regard to the fetus, hyperglycemia and acidosis are a greater threat than hypoglycemia. Of 5 patients with acidosis, 4 bore macerated stillbirths or miscarriages. Four-

Graph showing viability and weight of babies of diabetic mothers

teen of our patients had hypoglycemic reactions, some reaching coma. The time of these reactions with reference to gestation was from the second month to the day before delivery. All these 14 patients bore living babies. In view of these observations we are inclined not to be unduly concerned in the presence of maternal hypoglycemia.

An increase in tolerance for glucose is often noted at the time of labor. As has been pointed out by others, this may result from the increase in activity of voluntary muscles and from uterine contractions. The insulin requirement of a given patient is often reduced materially at this time, a circumstance calling for a reduction in its dosage in order to avoid possible hypoglycemic reactions during labor. It is our practice to decrease by half the initial dose of insulin at the onset of labor, giving additional insulin as indicated by the results of study of the sugar of the urine and blood and the carbon dioxide combining power. In 2 patients with hypoglycemia in labor, the fetal blood taken at the same time showed an extremely low level of sugar. Clinically, however, these infants behaved normally and showed no evidence of hypoglycemia.

Labor and puerperium Labor and the puerperium give rise to peculiar problems in the diabetic. Labor is critical. Anesthesia, especially with ether or chloroform, tends to induce coma. The exertions of parturition have a like effect in reducing the reserve of

TABLE VII—FETAL DEATHS

been inadequate for this reason. Only 21 patients had been managed for adequate periods by the accepted methods at the Sloane Hospital. These periods varied from the full 9 months of gestation to a minimum of 2 months.

The fetus. In this series there were 11 still births and neonatal deaths and 4 spontaneous abortions. The causes of these accidents are set forth in Table VII.

With regard to the size of the fetus of the diabetic mother, our experience as illustrated by the accompanying graph showing viable births, does not bear out commonly accepted ideas. The graph shows that the child of the diabetic mother is as likely to be underweight as overweight. Of the viable births 12.2 per cent were underweight and 26.5 overweight. Among the babies of an equal number of unselected normal mothers 18.0 per cent were overweight. In the zone of weights between 5 and 8½ pounds there seems to be a slight preponderance of large babies in the group of normal as compared with diabetic mothers.

In our series, 41 were delivered normally or by means of forceps. Of these 11 were still births or neonatal deaths: 5 premature and 6

at term. The mode of delivery in the 11 was normal in 5, by forceps in 5 and cesarean section in 1. In 5 of the stillbirths the fetal weight was 5 pounds or less, in 3, from 6 pounds 14 ounces to 11 pounds 11 ounces. Two of the deaths were due to obstetrical causes, namely, prolapsed cord and Bandl's ring. 1 was due to toxemia.

Treatment. During pregnancy the diabetic patient presents several therapeutic pitfalls. The vomiting of early pregnancy augments the danger of diabetic acidosis, so that a serious ketosis may develop rapidly. In some such cases abortion may occur before coma. For this reason the regulation of diet and insulin in the first trimester may be difficult or even impossible. Here a high carbohydrate intake is best adapted to the treatment of both the ketosis of diabetes and the vomiting of pregnancy.

Regardless of the previous diet of the patient it has been our general practice to attempt to supply 200 grams of carbohydrate daily to the diabetic patient with vomiting of pregnancy. This is given in 5 or 6 feedings at 2 hour intervals and insulin is given as often as indicated by the results of urinalysis and

the child in advance of term, the total mortality in our cases was 28.3 per cent. Included in these figures are 4 spontaneous abortions in 9 inadequately treated diabetic mothers, and 4 with serious added obstetric complications such as Bandl's ring, prolapsed cord, and large fibromyomas. Excluding cases of this kind the corrected mortality is 3.7 per cent, a figure differing little from that of the general hospital admissions

SUMMARY AND CONCLUSIONS

In an experience with the care of 56 patients with diabetes in 67 pregnancies we have been impressed with certain phases of the condition. In the first place, a family history of diabetes occurred in 17.8 per cent. Of equally common occurrence was a family history of vascular disease.

In none of the patients did the disease begin before puberty, so far as we could ascertain. In 15 cases, a larger proportion than is usually reported, the disease began during pregnancy.

The past obstetrical history is striking. There is a story of repeated stillbirths, abortions, and neonatal deaths. The reproductive capacity of these patients is low. The incidence of vascular disease and hyperthyroidism is high.

Under the conditions of a well organized clinic, the diabetic mother may be carried through pregnancy with little added risk.

Further, there is a reasonably good chance of a viable infant provided the maternal care is adequate. Conversely, the fetal mortality in diabetes not adequately supervised and treated remains high. The striking liability of the diabetic woman to late toxemia should be emphasized. This seems a significant association. The internist has long surmised that vascular disease with hypertension is related to diabetes, and has noted the tendency of diabetes and hypertension to dwell in the same individuals and families. Further, the relation of late toxemia of pregnancy to vascular disease has been established. For this reason, the frequent association of diabetes with the vascular types of pregnancy toxemia is of more than casual significance.

The fetus of the diabetic mother is quite as likely to be underweight as overweight.

In our judgment the routine performance of cesarean section in uncomplicated maternal diabetes is unwise. This operation should be reserved for those cases in which there is a supporting obstetric indication.

glycogen and alkali, thus promoting hypoglycemia, acidosis, and its consequences

In our cases the hazard of infection seems to be as pronounced as in those reported elsewhere. There was a puerperal morbidity of 41 per cent, as judged by our standard—a temperature of 100.4 degrees for two consecutive readings after the first 24 hours following delivery. This diagnosis was made in 14 with out any specific infection having been recognized. Two were diagnosed as endometritis, 1 as pyelitis, 1 as thrombophlebitis and 2 breast abscess.

Delivery. The mode of delivery in the 67 pregnancies is shown in Table VIII. Of the 67, 31 were delivered at term, 17 were premature, and 2 were overdue.

Among the 15 fetal deaths in both groups are included the spontaneous abortions. Of the 9 fetal deaths in the first group we consider diabetes the sole cause in 6. In the remaining 3 there were additional factors such as fibroids, lues, toxemia, and obesity.

In the second group that of adequately controlled diabetics, 6 fetal deaths occurred. Two were premature stillbirths. In 1 case there were multiple fibroids, in another fibroids and hyperthyroidism. In the 2 remaining, Bandl's ring and prolapsed cord. It will be noted that when fetal death occurred in diabetics adequately controlled a factor other than the diabetes was present.

Cesarean section. The question of cesarean section in diabetes is of special importance. It should have discussion from the standpoint of the mother and of the fetus. In none of our cases was cesarean section undertaken because of the diabetes alone. The indications for the operation in these patients were for pelvic disproportion, 3; elective following stillbirth caused by Bandl's ring in a previous pregnancy, 1; for uterine inertia, 1, followed by a

second section in the same patient in a later pregnancy, for sterilization, 2.

Our experience inclines us to hesitancy in advising termination of pregnancy by cesarean section in the diabetic. In the first place if this measure were adopted generally in all cases in which the diagnosis of diabetes in pregnancy might be made, a way would be opened to the commission of numerous errors. Among possible mistakes, that of diagnosis is not unimportant. Without adequate experience and laboratory equipment examples of renal glycosuria, lactosuria or non-diabetic acidosis in pregnancy may be mistaken for true diabetes and the patient subjected to needless surgical hazard.

Since we have had no maternal deaths in diabetes during pregnancy, the puerperium, or the follow up we can find no strong argument for radical methods of delivery in this disease, at least from the standpoint of maternal security.

At this point one might recall the fact that the general maternal mortality for this operation as given by P. H. Bland¹ is 6.5 per cent.

These facts tend to discourage the early or artificial termination of pregnancy as a general measure in diabetes.

The fact that a diabetic mother loses her fetus is not necessarily proof that the metabolic disorder is responsible for the unsuccessful pregnancy. In all such instances one should investigate such frequent causes of fetal death as toxemia, lues, hyperthyroidism, vitamin deficiency, uterine fibroids, or hormonal defects any of which may be co-existent.

On the side of the fetus cesarean section is a more debatable matter. Can this operation diminish the frequency of fetal death in diabetes? Since it has been stated that the obstetrician's answer to diabetes is cesarean section shortly after viability to save the child, the ordinary fetal risks of this procedure might be recalled. It should be considered that every baby delivered by this dictum is premature. In a review of 300 cases of prematurity, Wilcox reports a gross mortality of 25 per cent regardless of the method of delivery. Without interrupting the pregnancy in the interests of

authors may be reconciled when we remember that one speaks of the condition of things in the living subject and another in the dead. The knowledge of one is gained in the clinic, of the other in the dissection room." It was then that Henle wrote that deductions based upon frozen sections were of no value as both the consistency and the position of the uterus were altered after death, for in life the tone of the muscles and the filled blood vessels were of importance in establishing the position of the uterus

In 1863 Luschka described the organized muscle fascia rich in elastic tissue that makes up the broad ligaments together with the many blood vessels and lymphatics in the lower part of the ligaments. He traced out the formation of the muscle fibers from the folds of Douglas to their insertion in the lower end of the uterus and vagina which "helped to fix the position of the uterus," and called these ligaments the "retractor uteri." Virchow demonstrated later that many of the muscle fibers in the uterosacral ligaments extend along the sides of the uterus and join with muscle fibers from the anterior face of the uterus to make up the thin layer of muscle in the uteropubic fascial plane on which the bladder rests. The position and axis of the uterus continued to be the subject of discussion and debate

It was in 1880 that Kocks when a *Privatdozent* in the University of Bonn, wrote his monograph in which he discussed the normal and pathological position and shape of the uterus, and its mechanics. In this discussion, today a classic in gynecology, Kocks described the positions of the uterus, answering the arguments for and against the various displacements as found in frozen sections or as found on palpation in the living. His opinion was that the uterus has no absolute, but a relative, position. His arguments against the positions as found at postmortem, are that in the living (1) there is a positive abdominal pressure, (2) that the influence of inspiration and expiration must be considered, (3) in the ligamentous apparatus of the pelvic organs the connective tissue which binds them together has a certain degree of "turgescence" which is lost after death, and finally (4) the

Fig 1 Cardinal transverse horizontal axis (From Kocks)

muscle elements in the ligaments act with sufficient force in the living to influence the position of the uterus.

Kocks described the mechanics of the pelvis and says, "The bases of the broad ligaments build the axis of the uterus and because of their importance should be called the cardinal ligaments. They build, according to my thinking, the material 'substrat' of the axis and account for the normal anteversion of the uterus." He called the base of the broad ligaments the "cardinal transverse horizontal axis" and said on this axis the uterus turns as on a lever with two arms (Fig. 1). The anterior longer arm (*a-b*) is the position of the uterus in young women or in nulliparae. The posterior shorter arm (*a-c*) is the position of the uterus after pregnancy has occurred. The uterus then has a longer axis upward due to its increase in size and sinks lower toward the vaginal outlet as a result of the softening of the pelvic tissues, and it is not as sharply bent forward as in a nullipara. The intra-abdominal pressure is greater on the axis *a-c*, but may be equal in both axes under certain conditions

In a summing up of the position and mechanics of the uterus, Kocks gives such an exact and concise description, I will quote in its entirety. He says: "The upper pelvic floor consists of the bases of the broad ligaments,

THE UPPER PELVIC FLOOR AND ITS IMPORTANCE IN TOTAL ABDOMINAL HYSTERECTOMY

LILIAN K. P. FARRAR, A.B., M.D., F.A.C.S. New York, New York

IN 1888 von Bardeleben, of Jena, reviewed the literature pertaining to gynecology from the time of Leonardo da Vinci ("Der Allseits Median Schnitt") up to and including his own period and characterized the writings "with few exceptions" up to the middle of 1800 as "so gut wie nichts." He states that in the year 1854 there were published three papers by three different physicians, each in a different country which laid the foundation of gynecology. Kohlrausch published in Leipzig *Zur Anatomie und Physiologie der Beckenorgane*. He said that the position of the uterus was dependent upon the fullness of bladder and rectum and that the cervix was fastened to the bladder by a light reticular plane of connective tissue. The second paper was printed in the *Gazette médicale de Paris* and was an exposition by Cruveilhier on the autopsy of a young woman who had died following the repeated use, for several days, of an indwelling catheter introduced into the uterus to correct a sharp antelexion. Cruveilhier said that disease produced malposition of the uterus but that malposition existed without symptoms and did not produce disease. In the discussions with Arvard at this time, Cruveilhier gave his opinion, based upon autopsies, that there was no established normal position for the non-pregnant uterus. Arvard, who had palpated and moved the uterus in the living, and found that it would immediately return to position, claimed that an angle of 75 degrees with the horizon was the normal position for the uterus. The third paper was written by Matthews Duncan, and appeared in the *Edinburgh Medical and Surgical Journal* of that same year. It was entitled "On the Displacement of the Uterus." Duncan affirmed that, "Death was not a good criterion as so much depended upon muscular tonicity and vascular turgescence which dis-

appeared with life." Duncan also wrote "A uterus that is not mobile is in a pathological state." This is the beginning of the study of anatomy, physiology, and pathology of the pelvic organs in women.

In the *History and Bibliography of Anatomic Illustrations* written by Ludwig Choulant he writes "The great universal genius Leonardo da Vinci illustrated the fetus in its natural position from direct personal observation and not until William Smellie in 1754 and William Hunter in 1774, both of London, published their monumental volumes do we actually find illustrations of the fetus *in utero* which were really observed and faultlessly reproduced from an anatomical point of view." There are even fewer illustrations of the non-pregnant uterus, but da Vinci has one showing graphically the blood vessels of the uterus, and Versalius has one plate in his work on the human body of the fusion of the muellian ducts, and the uterus complete with the cervix, vagina and urethra. In 1754 William Smellie published with the set of anatomical tables his "*Practice of Midwifery*." In this work is one illustration of real historic value in gynecology as it shows the uterus supported on the vagina as it was at that time commonly believed to be. It is of interest to note that the artist (Pieter Camper) drew the course of muscle fibers from vagina to broad ligament. These colpopaginal muscle fibers were not utilized in plastic work on the vagina until more than a hundred years later.

While so little was done for gynecology by the anatomists immediately following Smellie, the study of pelvic conditions in women was greatly stimulated by the publications of Kohlrausch, Cruveilhier, and Duncan. The greater part of the research was done on frozen sections and naturally to a much less degree on the living. The reports were so at variance that Marion Sims wrote "I would say therefore that some of the discrepancies of the

authors may be reconciled when we remember that one speaks of the condition of things in the living subject and another in the dead. The knowledge of one is gained in the clinic, of the other in the dissection room." It was then that Henle wrote that deductions based upon frozen sections were of no value as both the consistency and the position of the uterus were altered after death, for in life the tone of the muscles and the filled blood vessels were of importance in establishing the position of the uterus.

In 1863 Luschka described the organized muscle fascia rich in elastic tissue that makes up the broad ligaments together with the many blood vessels and lymphatics in the lower part of the ligaments. He traced out the formation of the muscle fibers from the folds of Douglas to their insertion in the lower end of the uterus and vagina which "helped to fix the position of the uterus," and called these ligaments the "retractor uteri." Virchow demonstrated later that many of the muscle fibers in the uterosacral ligaments extend along the sides of the uterus and join with muscle fibers from the anterior face of the uterus to make up the thin layer of muscle in the uteropubic fascial plane on which the bladder rests. The position and axis of the uterus continued to be the subject of discussion and debate.

It was in 1880 that Kocks when a *Privatdozent* in the University of Bonn, wrote his monograph in which he discussed the normal and pathological position and shape of the uterus, and its mechanics. In this discussion, today a classic in gynecology, Kocks described the positions of the uterus, answering the arguments for and against the various displacements as found in frozen sections or as found on palpation in the living. His opinion was that the uterus has no absolute, but a relative, position. His arguments against the positions as found at postmortem, are that in the living (1) there is a positive abdominal pressure, (2) that the influence of inspiration and expiration must be considered, (3) in the ligamentous apparatus of the pelvic organs the connective tissue which binds them together has a certain degree of "turgescence" which is lost after death, and finally (4) the

Fig 1 Cardinal transverse horizontal axis (From Kocks)

muscle elements in the ligaments act with sufficient force in the living to influence the position of the uterus.

Kocks described the mechanics of the pelvis and says, "The bases of the broad ligaments build the axis of the uterus and because of their importance should be called the cardinal ligaments. They build, according to my thinking, the material 'substrat' of the axis and account for the normal anteversion of the uterus." He called the base of the broad ligaments the "cardinal transverse horizontal axis" and said on this axis the uterus turns as on a lever with two arms (Fig. 1). The anterior longer arm (*a-b*) is the position of the uterus in young women or in nulliparae. The posterior shorter arm (*a-c*) is the position of the uterus after pregnancy has occurred. The uterus then has a longer axis upward due to its increase in size and sinks lower toward the vaginal outlet as a result of the softening of the pelvic tissues, and it is not as sharply bent forward as in a nullipara. The intra-abdominal pressure is greater on the axis *a-c*, but may be equal in both axes under certain conditions.

In a summing up of the position and mechanics of the uterus, Kocks gives such an exact and concise description, I will quote in its entirety. He says: "The upper pelvic floor consists of the bases of the broad ligaments,

Fig. 2 Uterosacral ligaments uteropubic fascial plane and the levator ani muscle

the uterine end of the ligamentum sacro uteri, the ligamentum vesico uteri, the posterior wall of the bladder, and the anterior wall of the rectum, all of which are bound together by connective tissue fibers and covered with peritoneum and inserted into the uterus at the height of the internal os. The finger thick bases of the broad ligaments form the true lever (*Drehpunkte*) for the mechanics of the uterus."

Two years after Kocks monograph Berry Hart of Edinburgh published his atlas and at about the same time Savage of London, brought out his beautifully colored plates of the pelvic organs in women. Berry Hart described the fibromuscular tissue of the uterosacral ligaments as alike in structure with the broad ligaments with which they are joined differing only in the greater proportion (Fig. 2) of muscle in the uterosacral ligaments and in the great amount of elastic tissue through out the broad ligaments and the connective tissue at their base. The uterosacral ligaments have at their upper border a flat fold of muscle fascia that extends from the uterus to the rectum and if one wishes to be anatomically correct they should be called uterorectal ligaments. The true uterosacral ligaments lie just below these two folds and extend (on each side of the rectum) from about the third sacral vertebra to be inserted into the posterior surface of the uterus at the height of the internal os. This insertion of the ligaments extends down the entire posterior cervix and then down to be inserted into the posterior wall of

the vagina. It is due to the thickness of these muscles and to their insertion into the posterior cervix and vagina that the uterosacral ligaments become the strongest factor in the upper pelvic floor that influences the position of the uterus. Luschka rightly termed them the "retractor uteri."

The elastic tissue in the broad ligaments allows of movement of the tissues themselves and of displacement of the uterus laterally or posteriorly or for growth of the uterus upward without disturbance or injury of the structures within the broad ligaments. The anterior portion of the upper pelvic floor is composed of light reticular fascia and the uteropubic fascial plane on which the bladder rests is made up of connective tissue with only a thin layer of muscle and almost no elastic tissue. It is for this reason that the powerful muscles in the uterosacral ligaments can influence the position and direction of the descending head in labor as proved by x ray studies made by Caldwell and Moloy. It is also the reason why the most common and often the only visible injury after labor is a resulting cystocele due to the pressure on the uteropubic fascial plane which splits longitudinally and its torn edges (so erroneously called the "pillars of the bladder") stretch apart from the continued intra abdominal pressure. The bladder forced by prolonged pressure from above slips through the gap in the torn fascial plane just as a loop of intestine does in a hernia.

The connective tissue in the base of the broad ligaments was well described first by Savage who wrote "The uterine system may be conceived as having been thrust into the pelvis between the rectum and bladder and there fixing itself by cellular attachments to every available part of the pelvic cavity." Savage was also the first to note that infection in the broad ligaments long remained local without involvement of the ureter, rectum, or bladder. He also showed that the uterine cellular system is continuous at its periphery with every part of the subperitoneal cellular tissue at the lower part of the abdomen.

The beautiful illustrations in the atlas by Sappey of his work on the lymphatics of the body depict the glands lying in the broad

ligaments and the course of the lymphatics from the uterus. The importance of removing these glands in the broad ligaments was stressed by Wertheim when performing hysterectomy for cancer of the cervix.

In 1885 Freund published his work on the connective tissue of the pelvis and the result of an inflammation that involves it, and Testut later described the "phlegmons" or abscesses of the broad ligaments with the four routes of approach: (1) Vaginal route—by incision direct without opening the peritoneum; (2) perineal route of Hegar and Saenger that crosses the ischiorectal fossa and levator ani; (3) parasacral route of Zuckerkandl and Wolfer and is made at the border of the sacrum upon the sides of the rectum; (4) abdominal *sous peritoneale* of Pozzi

The sympathetic ganglia lying on the posterior leaves of the broad ligaments had been demonstrated as early as 1867 by Frankenhauser, their location he believes accounts for the fact that operations on the posterior pelvis produce more shock than operations on the anterior pelvis. Undoubtedly this fact explains why less shock is associated with a vaginal hysterectomy than with an abdominal hysterectomy for in vaginal hysterectomy there is not nearly so great an invasion and injury by clamps to the broad ligaments as there is in the abdominal operation.

In 1894 Mackenrodt, of Berlin, wrote concerning the normal and pathological positions of the uterus and he described the tissues of the broad ligament which he called the *Ligamentum transversale colli*. This ligament (*band*) has been the subject of much discussion and several papers have been written denying its existence, the reason being, I believe, a misconception of Mackenrodt's use of the word *band*. The illustration published in the same issue of the *Archives fuer Gynaekologie* certainly leaves no doubt that Mackenrodt intended the entire broad ligament as the *Ligamentum transversale colli*. Mackenrodt's exposition of the tissues in the broad ligament adds nothing to the work of the previous writers but is of value inasmuch as he maintains that the broad ligaments are the supporting structures of the uterus. The objection is often made that the tissues described by both Kocks and Macken-

rodt are not true ligaments, and this may explain why their studies have not received more recognition.

In 1899 Waldeyer, of Berlin, in his great work *Das Becken* showed by illustrations the embryological and anatomical formation of the structures composing the broad ligaments: (a) The three ligaments that lie on each side of the uterus in the folds of the broad ligaments begin early in embryological life as two strands of tissue that cross (one on each side) the muellerian ducts. Later in fetal life having derived muscle from the outer coat of the uterus, the anterior portion of each strand of tissue becomes a round ligament, similar to the "gubernaculum" of John Hunter, and composed of muscle and elastic tissue in its upper half and of connective tissue in the lower half where it is attached to the pubic bone and labia majora. Berry-Hart, in his interesting work, has traced the physiological descent of both the ovaries and testes in the human fetus and says the descent of the ovary is analogous to that of the testes, but its further descent in the pelvis is checked by the broad ligament and the uterus. In the adult female, the ovaries lie on the posterior aspect of the broad ligament, on the lateral pelvic wall in front of the sacro-iliac joints, immediately below the ileopectineal line, and with the ureter curving behind. The pelvic ectopia testis is analogous to the normal position of the ovaries. The inguinal and lateral ectopia ovarii are normal stages for the testes. Waldeyer showed that the upper part of the strands of embryonic tissue take their muscle from the uterus and are continued as the ovarian ligament and then as the infundibulo pelvic ligament. If the ovaries are to be left *in situ* when a hysterectomy is performed, the ovarian ligaments (by virtue of this muscle) should be fastened to the vaginal or cervical wound before it is closed.

Luschka (in 1863) first called attention to the proximity of the ureter to the ovary just as the ureter is about to enter the broad ligament where it lies superficially under the posterior leaf of the broad ligament to which it is attached. The ureter continues directly under the hilum of the ovary to which it is often adherent and as it emerges from the broad

ligament lies close to the vaginal plexus of veins. The origin of the base of the broad ligament is shown by Waldyer to be from the uterus at the height of the internal os. The muscle is derived from the outer muscular coat of the uterus as shown by Pietro Sue (in 1600). Its fibers extend from the uterus transversely and obliquely to the pelvic wall, and laterally are continuous with the adjacent tissues. There is no line of demarcation between this muscle and the uterus and no attachment of the broad ligament to the uterus as it is sometimes stated in textbooks. The connective tissue sheaths of veins, lymphatics, blood vessels, and ureters run more or less obliquely from back forward and from above downward through the broad ligaments strengthening them but not fixing the tissues rigidly, for the great amount of elastic tissue present in the folds of the ligaments permits considerable movement of these sheaths and allows for the growth of the uterus upward in pregnancy or for lateral or posterior displacements of the uterus or for its enlargement by tumors.

An excellent description of the external appearance of the broad ligament is given by Testut who says "The broad ligament consists of two folds of peritoneum as they leave the sides of the uterus in close apposition one to the other for a part of the distance to the lateral walls of the pelvis. They form a sheet of tissue irregularly quadrilateral the upper border of which is free, thin, and mobile, the other borders of which are thick and attached to the lateral wall of the pelvis and to the upper pelvic floor and to the sides of the uterus. This sheet of tissue forms on each side of the uterus—two wings to the uterus, as it were, and consists only of the broad ligaments. (a) The anterior face of the broad ligament looks forward and downward, (b) the posterior face, which is larger, looks backward and upward and envelops part of the ovary and its ligament, the mesosalpinx and the hooded cap of the ovary, (c) the superior border encloses the fallopian tube, ovary, and its ligaments, (d) the inferior border, the thickest of the four borders, rests on the upper pelvic floor. (It is in close contact with the lateral cul de sac of the vagina. It contains the ureter and the horizontal part of the uterine artery), (e) the

internal border, thick and short, rests at the side of the uterus, it contains the ascending part of the uterine artery and the venous plexus, (f) the external border, relatively thin, rests at the lateral wall of the pelvis. In the upper part between the pavilion of the tube and the external extremity of the ovary it is free and *flottant*. Below the ovary it adheres closely to the pelvic wall near the obturator internus and its aponeurosis and at the extremity of the ovary it continues as the infundibulopelvic ligament, the ilio ovarian ligament, or the lumbar ovarian ligament. It lodges the ovarian artery and vessels and contains smooth muscle (Luschka's 'retractor of the fallopian tube'). It crosses the iliac vessels, then the border of the psoas muscle to the lumbar region. Anatomically the broad ligament is composed essentially of two leaves of serous tissue with a sheet of smooth muscle united one with the other by a bed of cellular vascular tissue. A sagittal section shows it consists of (a) the mesosalpinx—two leaves of peritoneum between which is a bed of cellular elastic tissue and some blood vessels, (b) the base of the broad ligament—lymphatics, cellular tissue, blood vessels."

The relation of the structures in the broad ligaments to one another and to the adjacent structures is shown in an admirable dissection (Fig 3) made by Sellheim. Comparative anatomy of the female pelvic organs has seldom been described and never more beautifully illustrated than in his dissections (Fig 4). If we bear in mind, as Blair Bell has said, the important fact that there are no aponeurotic fascias except in relation to muscle surfaces (Fig 5) and that when fascia comes into relation with blood vessels, lymphatics or nerves it forms fibrous bands and sheaths. This increases the supporting power of the structures in the broad ligaments. Add to this the fact that the levator ani (Fig 6) arises from the back of the pubic bone and the fascia on the internal surface of the compressor urethrae with which its fascial coverings are blended, that its superior fascial covering is attached to the aponeurosis of that of the muscles above, and posteriorly its aponeurosis is adherent to the ischial spine and continues to the side and anterior surface

Fig 3 Cross section at about the first sacral vertebra showing the broad ligament and its relation to the obturator internus muscle, etc (After Sellheim)

of the coccyx where the fascias from either side unite in the midline. Thus the whole upper floor forms a united structure for the support of the uterus.

Fig 4 Cross section 2 centimeters below that in the preceding illustration showing the broad ligament and its relation to the obturator internus muscle and the sheaths of the nerve trunks (After Sellheim)

The tissues in the broad ligament vary greatly even in young women, depending upon the age, general constitution, and muscular development. Their vascularity and elasticity are greatly increased during pregnancy. In the normally developed young woman and in

Fig 5 Cross section 2 centimeters below that in the preceding illustration showing the cardinal ligament and its relation to the pyriform, internal obturator, and levator ani muscles, the sheaths of nerves, ureter, and blood vessels (After Sellheim)

ligament lies close to the vaginal plexus of veins. The origin of the base of the broad ligament is shown by Waldeyer to be from the uterus at the height of the internal os. The muscle is derived from the outer muscular coat of the uterus as shown by Pietro Sue (in 1600). Its fibers extend from the uterus transversely and obliquely to the pelvic wall, and laterally are continuous with the adjacent tissues. There is no line of demarcation between this muscle and the uterus and no attachment of the broad ligament to the uterus as it is sometimes stated in textbooks. The connective tissue sheaths of veins, lymphatics, blood vessels, and ureters run more or less obliquely from back forward and from above downward through the broad ligaments strengthening them but not fixing the tissues rigidly, for the great amount of elastic tissue present in the folds of the ligaments permits considerable movement of these sheaths and allows for the growth of the uterus upward in pregnancy or for lateral or posterior displacements of the uterus or for its enlargement by tumors.

An excellent description of the external appearance of the broad ligament is given by Testut who says "The broad ligament consists of two folds of peritoneum as they leave the sides of the uterus in close apposition one to the other for a part of the distance to the lateral walls of the pelvis. They form a sheet of tissue irregularly quadrilateral the upper border of which is free, thin, and mobile, the other borders of which are thick and attached to the lateral wall of the pelvis and to the upper pelvic floor and to the sides of the uterus."

This sheet of tissue forms on each side of the uterus—two wings to the uterus as it were, and consists only of the broad ligaments. (a) The anterior face of the broad ligament looks forward and downward. (b) the posterior face, which is larger, looks backward and upward and envelops part of the ovary and its ligament, the mesosalpinx and the hooded cap of the ovary, (c) the superior border encloses the fallopian tube, ovary, and its ligaments. (d) the inferior border, the thickest of the four borders, rests on the upper pelvic floor. (It is in close contact with the lateral cul de sac of the vagina. It contains the ureter and the horizontal part of the uterine artery), (e) the

internal border, thick and short, rests at the side of the uterus, it contains the ascending part of the uterine artery and the vaginal plexus, (f) the external border, relatively thin, rests at the lateral wall of the pelvis. In the upper part between the pavilion of the tube and the external extremity of the ovary it is free and *flottant*. Below the ovary it adheres closely to the pelvic wall near the obturator internus and its aponeurosis and at the extremity of the ovary it continues as the broad ligament, the broad ovarian ligament, or the lumbar ovarian ligament. It lodges the ovarian artery and vessels and contains smooth muscle (Luschka's "retractor of the fallopian tube"). It crosses the iliac vessels, then the border of the psoas muscle to the lumbar region. Anatomically the broad ligament is composed essentially of two leaves of serous tissue with a sheet of smooth muscle united one with the other by a bed of cellular vascular tissue. A sagittal section shows it consists of (a) the mesosalpinx—two leaves of peritoneum, between which is a bed of cellular elastic tissue and some blood vessels, (b) the base of the broad ligament—lymphatics, cellular tissue blood vessels.

The relation of the structures in the broad ligaments to one another and to the adjacent structures is shown in an admirable dissection (Fig. 3) made by Sellheim. Comparative anatomy of the female pelvic organs has seldom been described and never more beautifully illustrated than in his dissections (Fig. 4). If we bear in mind, as Blair Bell has said, the important fact that there are no aponeurotic fascias except in relation to muscle surfaces (Fig. 5) and that when fascia comes into relation with blood vessels lymphatics or nerves it forms fibrous bands and sheaths. This increases the supporting power of the structures in the broad ligaments. Add to this the fact that the levator ani (Fig. 6) arises from the back of the pubic bone and the fascia on the internal surface of the compress or urethra with which its fascial coverings are blended that its superior fascial covering is attached to the aponeurosis of that of the muscles above and posteriorly its aponeurosis is adherent to the ischial spine and continues to the side and anterior surface

nulliparae the broad ligaments are soft, firm, and only moderately yielding to pressure, unless examined when the individual is under an anesthetic. In multiparae the tissues are thicker and less resistant. In the aged the muscles are much thinner and the uterus is more readily displaced downward, due not always to torn muscle, but as well to the loss of the very large amount of elastic tissue normally present in younger women. If fibroids have developed in the uterus, the tissue of the broad ligaments may have the same firmness as the uterine tissue and when taking out such a uterus in an abdominal hysterectomy it may be as hard to cut as gristle. The effect of inflammation or suppuration in the parametrium may be to leave a chronically thickened tissue across the base of the upper pelvic floor. The development of connective tissue and its supporting effect may be seen after the radium treatment of a cancer of the cervix, the vault of the vagina may become narrow in width and much thickened with no prolapse of the now shrunk-cervix, although perhaps below the irradiated tissues a gaping vulvar orifice with a large cystocele and rectocele bulging into the vagina may be seen. From all this it is plain that the development and character of the tissues in the broad ligaments vary greatly in the living, depending not only upon age and constitution but also upon the effect of injuries incident to labor, of loss of muscular tone and elasticity, and to inflammation or tumor growth. All of these factors should be taken into consideration before an operation is undertaken. As von Bardeleben said many years ago: "Anatomy is not the knowledge of a cadaver, nor of dead tissues, but it is a part of the knowledge we have of the living."

It was not until nearly the end of 1800 that surgeons began to use the paracervical and paravaginal tissues in repair of prolapse of the uterus. In 1887-1888 Ernst Cohn, of Berlin, published the results obtained by Schroeder and Olshausen who in such cases performed anterior or posterior colporrhaphy and in a few cases the combined operation, of anterior and posterior colporrhaphy. In 1888 Archibald Donald, of Manchester, England, for the first time, amputated the cervix and then did an anterior and posterior colporrha-

phy on the same patient. Donald published his first report in 1902, and in 1903 Alexandroff, of Smolensk, Russia, described his technique of bringing the base of the broad ligaments from either side of the cervix and suturing them to one another and to the anterior surface of the cervix. It is of further interest that in the years 1907, 1908, 1909, surgeons of different countries should so nearly duplicate their knowledge and use of these tissues in prolapse. In 1907 Halban and Tandler published their work on the anatomy and etiology of genital prolapse in women; they stated that the levator ani and the associated muscles are the essential factors in keeping the uterus in place. In 1908, Fothergill, of Manchester, who has continued to practice the technique first used by Donald and now called the technique of the Manchester School, wrote "The Supports of the Pelvic Viscera." In a later paper Fothergill said: "Clinical experience gradually taught me that the uterus, vagina, and bladder are mainly kept in their place by the lateral combination of unstriated muscle and connective tissue known as the parametrium and the paracolpos." One year later William Mecklenburg Polk presented an address before the American Gynecological Society entitled "The Suprapubic Operation on the Upper Pelvic Floor for Prolapse of the Uterus." Since then two other members of this society namely, Robert L. Dickinson and Robert T. Frank have contributed much to our knowledge of the supporting tissues of the upper pelvic floor.

It is important therefore in total abdominal hysterectomy, to avoid, so far as possible, injury to the structures that lie in the depths of the upper pelvic floor and to utilize the supporting tissues in closure of the wound. First, hemorrhage from the vaginal venous plexus may be avoided by ligating the uterine artery, not only where it enters the uterus, but also before the vaginal and cervical branches are given off from the uterine artery. Second, injury to the sympathetic ganglia lying on the posterior leaf of the broad ligament may be avoided by cutting down the broad ligaments close to the sides of the uterus without applying any clamp to the broad ligaments (Fig. 7). Third by cutting the uterosacral muscles and

nulliparæ the broad ligaments are soft, firm, and only moderately yielding to pressure, unless examined when the individual is under an anesthetic. In multiparæ the tissues are thicker and less resistant. In the aged the muscles are much thinner and the uterus is more readily displaced downward, due not always to torn muscle, but as well to the loss of the very large amount of elastic tissue normally present in younger women. If fibroids have developed in the uterus, the tissue of the broad ligaments may have the same firmness as the uterine tissue and when taking out such a uterus in an abdominal hysterectomy it may be as hard to cut as gristle. The effect of inflammation or suppuration in the parametrium may be to leave a chronically thickened tissue across the base of the upper pelvic floor. The development of connective tissue and its supporting effect may be seen after the radium treatment of a cancer of the cervix; the vault of the vagina may become narrow in width and much thickened with no prolapse of the now shrunk-en cervix, although perhaps below the irradiated tissues a gaping vulvar orifice with a large cystocele and rectocele bulging into the vagina may be seen. From all this it is plain that the development and character of the tissues in the broad ligaments vary greatly in the living, depending not only upon age and constitution but also upon the effect of injuries incident to labor, of loss of muscular tone and elasticity, and to inflammation or tumor growth. All of these factors should be taken into consideration before an operation is undertaken. As von Bardeleben said many years ago. "Anatomy is not the knowledge of a cadaver, nor of dead tissues, but it is a part of the knowledge we have of the living."

It was not until nearly the end of 1800 that surgeons began to use the paracervical and paravaginal tissues in repair of prolapse of the uterus. In 1887-1888 Ernst Cohn, of Berlin, published the results obtained by Schroeder and Olshausen who in such cases performed anterior or posterior colporrhaphy and in a few cases the combined operation, of anterior and posterior colporrhaphy. In 1888 Archibald Donald, of Manchester, England, for the first time, amputated the cervix and then did an anterior and posterior colporrha-

phy on the same patient. Donald published his first report in 1902, and in 1903 Alexandroff, of Smolensk, Russia, described his technique of bringing the base of the broad ligaments from either side of the cervix and suturing them to one another and to the anterior surface of the cervix. It is of further interest that in the years 1907, 1908, 1909, surgeons of different countries should so nearly duplicate their knowledge and use of these tissues in prolapse. In 1907 Halban and Tandler published their work on the anatomy and etiology of genital prolapse in women; they stated that the levator ani and the associated muscles are the essential factors in keeping the uterus in place. In 1908, Fothergill, of Manchester, who has continued to practice the technique first used by Donald and now called the technique of the Manchester School, wrote "The Supports of the Pelvic Viscera." In a later paper Fothergill said: "Clinical experience gradually taught me that the uterus, vagina, and bladder are mainly kept in their place by the lateral combination of unstriated muscle and connective tissue known as the parametrium and the paracolpos." One year later William Mecklenburg Polk presented an address before the American Gynecological Society entitled "The Suprapubic Operation on the Upper Pelvic Floor for Prolapse of the Uterus." Since then two other members of this society namely, Robert L. Dickinson and Robert T. Frank have contributed much to our knowledge of the supporting tissues of the upper pelvic floor.

It is important therefore in total abdominal hysterectomy, to avoid, so far as possible, injury to the structures that lie in the depths of the upper pelvic floor and to utilize the supporting tissues in closure of the wound. First, hemorrhage from the vaginal venous plexus may be avoided by ligating the uterine artery, not only where it enters the uterus, but also before the vaginal and cervical branches are given off from the uterine artery. Second, injury to the sympathetic ganglia lying on the posterior leaf of the broad ligament may be avoided by cutting down the broad ligaments close to the sides of the uterus without applying any clamp to the broad ligaments (Fig. 7). Third by cutting the uterosacral muscles and

entering the vagina (Fig 8) posteriorly, the uterus will be loosened. A finger may be introduced into the vagina (this may be done safely if vagina has been properly scrubbed, douched, and iodized), which may act as a guide for the application of clamps to the vagina, thus insuring the cutting out of the uterus but eliminating the possibility of cutting too much of the broad ligament of injuring the ureters or bladder, of cutting into the uterus, and of leaving part of the cervix *in situ*. In this the technique resembles that of the usual vaginal hysterectomy. Fourth, careful closure of the vaginal wound. This should be done in an anteroposterior direction and not from side to side for the latter might cause distortion or injury to the ureters. The technique of closure should include (a) suture of the muscle walls of the vagina (b) the attaching to them of the round ligaments (Fig 9), uterosacral ligaments, ovarian ligaments if left, and the (Fig 10) uteropubic fascial plane, (c) the covering of the wound completely and exactly with the vesical peritoneum.

CONCLUSION

1. The upper pelvic floor is made of the unstriped muscle, elastic and connective tissue derived from, or attached to the lower part of the uterus and vagina. It includes the fibrous bands or sheaths of the nerves blood vessels lymphatics and ureters lying in the broad ligaments, the levator ani and its fascial coverings which are attached to that of the compressor urethræ anteriorly to the ischial spine and to the coccyx posteriorly and which blend with the aponeurosis of the muscles which lie above it in the broad ligament.

2. In total abdominal hysterectomy it is important to employ a technique by which one may remove the entire uterus without invasion of the broad ligament.

3. The tissues of the parametrium and paracolpos should be used to ensure a firm closure of the vaginal wound and to maintain the support of the upper pelvic floor.

BIOLOGICAL SURGERY IN TUBERCULOUS PATIENTS

Prof CARLOS ROBERTSON LAVALLE, F.A.C.S., Buenos Aires, Argentina

IT is a well known fact that every trauma to, or infection in, living tissue produces a reaction the severity of which depends upon whether the body is vulnerable or has been prepared by successive attacks to repel the inciting agent. For example, a primary attack of tuberculosis frequently produces in the human body an inflammatory reaction later to produce caseous lesions of varying intensity, known as the primary lesion of Ghon. The local reaction affects all the tissues and circulating fluids of the body, a fact well demonstrated by the von Pirquet test; here a positive reaction is obtained in the arm although the primary tuberculous focus may be located in the lungs.

If, however, the local caseous lesions resulting from the first attack remain quiescent and there is no other reaction on the part of the body, the patient may suffer a second attack by the Koch bacillus, resulting in tuberculosis of the bone, the lungs, the skin, or other part of the body. In the second attack, the Koch bacillus finds the tissues of the body altered—they have developed an allergy, the result of the first inoculation. The manner in which the reaction of the tissues is affected by the presence or absence of allergy is demonstrated in the production of the Koch phenomenon. In our experiment in producing the Koch phenomenon we used two guinea pigs. One of these had been successfully inoculated with a small injection of attenuated Koch bacilli a few months previously; consequently, it had a primary tuberculous lesion, in other words, a primary lesion of Ghon. The other guinea pig had received no preliminary injection of Koch bacillus and had no tuberculous focus. Both pigs were given subcutaneous injections of equal amounts of virulent Koch bacilli. The reaction in the two pigs was very different. In the first guinea pig, which had been previously inoculated with tuberculosis, in the first few days,

a black crust formed and fell off leaving an ulcerated area which was quickly filled in with cicatricial tissue. Thus the site at which the second injection had been made healed. In the second guinea pig which had received no previous injection of the Koch bacillus, the skin ulcerated within a month and the affected area became an extensive tuberculous ulcer, finally resulting in the death of the animal.

From these experiments it would seem that in the first animal, by virtue of having received a previous inoculation of the tubercle bacillus, the reaction of the plasma and circulating fluids had been modified; an allergic state developed which might be interpreted as an aggressive offensive against the new invaders. In other words, there was produced an immunization which was instrumental in curing the local lesion.

The experiment demonstrated clearly the phenomenon of Koch, namely, (1) that the primary inoculation is virgin soil free from tuberculosis, and (2) the re-inoculation in soil previously infected, caused dissimilar results: the first resulting in a caseous ulcer and the second in a cicatrix in tuberculous tissue without caseation. It is essential that the same tissue be used in both cases. The subcutaneous tissue, as in the experiment on the guinea pigs, is the most accessible and the most easily observed.

Almost every one from earliest childhood has a primary tuberculous lesion which is well tolerated. The lesion is usually in the form of a cicatrix with caseous material and with calcium salts frequently present, is about the size of a grain of wheat, and is sealed in the regional lymphatic ganglions. This sealed focus forms what is called the primary lesion of Ghon, which consists of live Koch bacilli of low virulence, and provides, during the life of the individual, substances which produce active immunization processes, like those which brought about the reaction in the guinea pig experiment.

Fig 1. Diagrams showing the operative procedure. In the drawing at top it is noted that the space between the spinous process and the transverse process on one side is thoroughly exposed. Hemostasis is obtained by pressure. The transverse process is then removed by bone rongeurs with the neck of the rib as a guide. The operator inserts the perforator through the exposed base of the transverse process with the pedicle vertically through the exact center to the depth of 1 inch—a distance equal to the anteroposterior segment of the spinal foramen at this level. Care is used to avoid penetrating the spinal canal. For that reason the body of the pedicle is used. With the point of the

Endogenous re infection in man probably arises from the reactivation of a Koch bacillus deposit which has remained dormant since the initial attack. This reactivation may take place in the selfsame primary lesion of Ghon or it may occur in any other site. The later re infection causes mild infections in the blood stream which are rapidly destroyed in the blood. At times, however, tissue in a state of lowered resistance may be involved or the re infection may be so overpowering that the natural defenses of the body provided by the lesion of Ghon will be overcome. In such instances the tubercle bacilli will colonize and thrive.

For 25 years we have sought diligently to find in the various tuberculous lesions in man these tuberculous re infection nuclei which stimulate the different tissues of the body to react so unexpectedly after having attained an allergic state. Such scars or nuclei we have chosen to call successively strangulated focus, chancre and now nucleus of post allergic focal infection.

We have found these nuclei in bone tissue and in the lungs. It is in aiding in the dispersion of the substances which are developed in these foci that we base our theory of treatment. At first we used the method only in cases of bone tuberculosis, today, however, we use the method in every case of tuberculosis whether it is of the lungs, the larynx, or other organs, the only exception being tuberculosis of the meninges.

Our first studies were made with animals first with tuberculous cows, then with dogs, rabbits and finally with guinea pigs. We used attenuated cultures of the Koch bacillus for inoculation material. Our experiments were carried on in large well equipped laboratories of the Instituto Modelo de Clin

perforator in the body of the vertebra the operator further inserts the perforator at an angle of 45 degrees and to the depth of 1 inch which is generally sufficient we fill the tunnel with an autogenous graft as a hemostatic measure. The caseous portions and the intervertebral disc are avoided. The middle drawing is a lateral view of the dorsal vertebra. In the bottom drawing of lumbar vertebra we note 1 the superior articular process has been removed by bone rongeurs, 2 the perforator is inserted for the first time and is shown reaching the interior of the pedicle, 3 the perforator has been inserted a second time and now reaches the middle of the body of the vertebra.

Fig 2 C S, before operation. A cavity the size of a penny and containing fluid is shown in the right apex. There is minute, nodular infiltration in the periphery and the paratracheal ganglia on the right side are very marked

Fig 3 C S, 14 months after operation. The nucleus of post allergic focal infection had been perforated but once with a trocar. The cavity has been replaced by cicatricial tissue, the hilar and paratracheal ganglia are diminished in size, fibrotic tendency is very marked. Patient does not cough, no Koch bacilli were found in the sputum and general condition is excellent

ica Medica of Buenos Aires, under the direction of Professor Luis Agote, who was the first in the world to use only citrated blood in blood transfusions in the human. After many months of study, however, all this material had to be abandoned, since we could not follow the development of the tuberculous processes for a sufficient length of time as in the human being and also the animals for experimentation were not of manageable size

We then began to devote our entire work to the minute observation of the pathological physiology in tuberculous lesions in knees which were obtained by transverse section of the human femur and tibia, our object being to note, centimeter by centimeter, any change in consistency, color, or quality of the blood at the different levels of resected bone. We studied especially the smaller and healthier portions rather than the portions with fatty degeneration, red or gray, with caseous necrosis, cavities

After persistent search our presumption was verified. within a section of the bone, there oozed forth under pressure a small quantity of black, thick, tar-like blood from a well

defined undermined spot, about a half centimeter in diameter. In addition we noted, adherent to the clot, an area of grayish tissue, resembling cicatricial tissue. Further studies revealed that this clot contained many attenuated tubercle bacilli which had become granular. The section showed an intense, specific reaction of the reticulo-endothelial system, as in caryocinesis. In the midst of a large quantity of collagenous substance, epithelioid cells formed Koester follicles but without caseous necrosis, that is, there developed a tuberculous tissue structure with great tendency to form one scar.¹

In roentgenograms of patients with tuberculous osteo-arthritis who have been treated with rest and heliotherapy only, we were able to prove that the appearance and size of the nucleus of post allergic focal infection did not change from year to year, but that the destructive process continued to progress throughout the extent of the bones forming the diseased joints. We have devoted much

¹See Tuberculosis quirurgica. Semana méd., 1935, No 30

Fig 4

Fig 5

Fig 6

Fig. 4 L. M. 30 years old before operation. Patient has had Pott's disease for 1 year. There was a large palpable iliac abscess and pulmonary tuberculosis. The first and second lumbar vertebrae were atrophied with blurred trabecular structure. The intervertebral disc is absent. Cheesy necrosis and wasting were noted in the lower half of the third lumbar vertebra in the upper middle part of which the nucleus is visible.

Fig. 5 L. M. 15 days after operation, which was performed in the presence of Dr. Albee of New York. The arrow marks the presence of a tunnel in the body of the third lumbar vertebra. This tunnel was made by the perforator which was inserted exactly to penetrate the nucleus of post allergic focal infection; the tunnel was bunged

with a little autobone graft as a hemostatic measure. There has been partial reabsorption of the caseous portions and the bony structures of the vertebra are well defined. Recalcification of the spinal column is noted as well as the presence of cortex and trabeculae.

Fig. 6 L. M. 8 months after operation. There is marked recalcification of the cortex and trabeculae. Cicatrization of the third lumbar vertebra is plainly visible and there is a tendency to fibrosis. The retraction of the scar pushes the third lumbar on the fourth due to the absence of the intervertebral disc. We do not apply casts and do not immobilize patients except when the cicatricial retraction is so great that marked kyphosis may result. The pulmonary tuberculosis is healed.

time to the study and observation of this focal point in roentgenograms. Interpretation has been made easier recently by the rapid advance and improvement in roentgen ray technique. This special focal point, this nucleus of post allergic focal infection, appears to us as a star shaped scar or agglomeration of tiny spots, the size of pin heads or small grains of rice. Here and there, however, the spots are always sharply outlined and resemble small metallic foreign bodies with rough edges and arranged often in the form of the spokes of a wheel. They usually are arranged in the form of an arc with three or four of the radii of the circle at equal intervals but the circle is not completed in the film.

If the peripheral or outside zones of the area supposed to contain or containing this nucleus of post allergic focal infection are

lightened with a solution of red aniline dye the common procedure in 'overcontrast' photographs, it is possible to obtain in prints of films a true picture of the nucleus with the characteristics noted.

We have sent to several hundred professors and to a total of 148 libraries of medical colleges of different states and countries films by which the characteristics of the nucleus of post allergic focal infection could be recognized.

In his book regarding local immunization¹ Besredka accepts Bichat's theory that there exist in each organ clusters of cells having the special ability to react not only anatomically but as well in their physiological functions. Thus Besredka and others have stated

Fig 7, left G L, Pott's disease (This was Case 75 of "My first 100 cases of Pott's disease reported in La Semana Medica, No 26, 1931.) The caseous necrosis and the destruction of 4 vertebrae, before operation. The intervertebral discs are absent. Patient was operated upon by perforating the first lumbar vertebral body. Patient was discharged a month later, walking without cast or support of any kind.

Fig 8 G L, 10 years after operation. The vertebrae formerly riddled with caseous necrosis, have now become transformed into a solid bone, rigid block. Patient is in very good condition, has no pains or contractions, and is fit for military service.

that certain cellular groups are susceptible to infection but become immunized even though the whole body responds, that is to say a tissue immunization exists. Confirming this theory of the elective tendency of certain cells against certain forms of infection of various virulence, we emphasize that we find that only one nucleus of post allergic focal infection exists in each case of osteo-arthritis, notwithstanding the fact that it may be formed by the combination of several diseased continuous bones. In coxalgia, for example, the nucleus, very large, is very often located below and to the inside of the antero-inferior iliac spine. In Pott's disease, the nucleus is very large and is located in the vertebral body near the point of implantation of both articular pedicle, often in the decalcified vertebra above or below the caseous necrotic focus. In doubtful case, it must have perforated two vertebrae. In knee it is small and very difficult to see.

We have presented here a process in which the body overcomes the local infection and exhibits a remarkable tendency, by virtue of large amounts of collagenous substance, to weaken the organisms which have established themselves and, by symbiosis, have begun to multiply. These bacilli do not reach the stage whereby they change the condition of tissue in which they are located because the body lessens their virulence. Furthermore, as has been accepted by many, there is formed in all "focal infections," a biological block that does not permit to pass the haptins, globulins (Landsteiner) or antibodies that in this instance are about to form autovaccines but allows to go through only the lysins (Maurice Nicolle), the poisons, which are more fluid, amino-acids. We maintain, then, that if there is an advantage locally, the system may suffer unless it is possible to free these imprisoned elements, elements capable

Fig 9

Fig 10

Fig 11

Fig 9 F V before operation Coxalgia. (This is Case 63 of the statistics presented at the Congress of Rosario 1934.) The roentgenogram discloses an enormous abscess clearly visible by opaque substances. Local heat, pain, edematous infiltration and adenitis were noted. The bone was so atrophied that it was almost transparent. The neck and head of the femur and articulating surface of the iliac bone and the cortex of the femur were considerably thinned.

Fig 10 F V 1 month after operation. A bone graft had been inserted making a tunnel in the neck and head of the femur and another one in the inside of the antero-

inferior iliac spine. The abscess was completely opened in the operation but closed later by primary intention. The pain has diminished and there is a decided improvement in the local and general condition. The iliac and femoral bones have become recalcified and are now more distinct. Patient discharged 4 months after operation, walking without cases of support.

Fig 11 F V 6 years later. Patient maintains his good general health. He has led an active life since discharge. Ankylosis is shown in the roentgenogram as well as marked recalcification and thickening of the cortex. There are visible beautifully marked lines of resistance in the femur

of forming autovaccines. Our experiences confirm the view of those among whom is professor Julio Mendes of Argentina, who believe that tuberculosis is principally a "focal infection." From such a focus lysins pass forth and, by greatly diminishing the defenses of the body, facilitate the caseous transformation of the new Koch bacilli localizations. For this reason I strive with my procedure to liberate the haptens for, when a nucleus of post allergic focal infection is perforated, it results in helping to reestablish the health of the patient, rapid detoxication and a tendency toward cicatrization of the existing lesions preceded by reabsorption of caseous material are noted and become more pronounced in the months following this comparatively simple operation.

The explanation of these phenomena is easy. The status of the nucleus of post allergic focal infection is changed completely by its perforation immediately the blood rushes in, the microbes suffer by the rude change in their culture medium, oxygen is rapidly

brought in and since oxygen does not favor the growth of tubercle bacilli they become weakened. The weakened bacilli, besides being easily affected by the lipolytic and proteolytic ferments, oxidases, etc., produce above all, weak antigens, namely autovaccines.

Since the patient carries these foci within himself—production centers of autovaccines—this action becomes continuous and prolonged, eventually diminishing the thickness of the new caseous masses. Meanwhile, nourished by the newly formed blood vessels, this material is transformed into whole lumps and, finally, into sclerosed, fibrous cicatricial masses.

Serological study shows that the Besredka and Vernes reactions are accentuated after the operation but frequently become negative in the following months when, clinically and roentgenographically, the patient is cured. In the days following puncture of the focus, the cutaneous reaction with von Pirquet's tuberculin becomes so marked that it generally takes the papular form, and sometimes

is hemorrhagic with extensive lymphangitis

A bacteriological and histological study of a tuberculous knee, operated upon by us 10 years previously, was made by Dr Vivoli, chief of the laboratory of the Hospital de Enfermedades Infecciosas, and Dr. Llambias, professor of pathological anatomy of the Faculty of Medicine of Buenos Aires. They both demonstrated the total absence of both the Koch bacillus and caseous material in the areas formerly carious but now refilled with compact, sclerosed cicatrices. In other words there was total elimination of the Koch bacillus; therefore the tuberculous infection had been cured.

It is generally admitted today that every tuberculous lesion, regardless of where it is located in the body, originated in the lung, or that tuberculosis was at one time manifest there.

The nucleus which is found in the lung, the nucleus of post allergic focal infection, is similar in every respect to that which we see in bone tuberculosis. In the lungs the nucleus is visible in well taken stereoscopic roentgenograms but only one is found for the two lungs, an observation which leads me to believe that it is a nucleus of post allergic focal infection. Quickly upon perforation of the nucleus detoxication begins and just as quickly or even more rapidly there follows in the succeeding months a transformation of the tuberculous caseation process into a fibrous and finally a cicatricial sclerosis. At the same time modifications of equal intensity occur in other tuberculous lesions of the body wherever located—in the joints, larynx, or even the intestines—regardless of how far away the perforated nucleus may be.

The operative technique is very simple once the nucleus of post allergic focal infection is visualized in stereoscopic roentgenograms, precise information is at hand as to the depth of the focus and we can then perforate the focus by the simple implantation of a bone autograft into the focus. The nucleus, which is always subcortical, may also be perforated by means of a trocar which may carry in the eye of its plunger various strands of catgut of different absorption dates, which may be left to fill the tunnel made by the needle in

the lung parenchyma. Catgut is not indispensable; the puncture tunnel in the lung is innocuous out of the hilum¹ and cheesy necrotic focus. These steps are sufficient to start the process of cure, in a few or many months, according to the extension and severity of the infection and the soil in which these lesions develop.

The reading of x-ray films to locate the nucleus of post allergic focal infection to operate upon is, and always will be, the essential and most vital point in this method of treating tuberculosis. Infinite care must be used and many stereoscopic roentgenograms must be made daily. Considerable practice in interpreting the roentgenograms is necessary to recognize in a shadow the outline of the scar and to determine its depth and location for guides in the perforation.

At first we were not as successful as we are at present. Our present figure is 76 per cent successful and we hope to better that even though we will use the method in grave cases. We used the method in Pott's disease 11 years² ago and we also have patients cured after the implantation of grafts in the lung 9 years ago. We can say, therefore, that our procedure has stood the test of time.

At our request the Faculty of Medicine of Buenos Aires appointed 8 professors, with the dean as president, as a committee to supervise operations and to study the results obtained, and after 6 months of work they made the following report:

Professor Robertson Lavalle's treatment of tuberculosis is simple and innocuous. In the patients whose progress we have followed after the operation, we have observed truly surprising results. We have examined patients operated upon previous to our appointment and their condition has remained satisfactory after application of this treatment.

(Signed) Professors José Arce (Dean), José A. Saralegui, Carlos Fonso Gandolfo, Raúl Arganaraz, Antonio R. Zambrini, Ludovico Facio, Enrique Castano, Ricardo E. Donovan.

After this report the University has in view creating a special institute where our method may be given a wider application.

THROMBOPHLEBITIS OF THE APPENDICIAL VEIN COMPLICATING ACUTE APPENDICITIS

STUART Z. HAWKES, M.D. M.Sc.D. Newark, New Jersey

APPENDICITIS is a disease of civilized peoples. Wherever it occurs, the mortality is high. Statistics for the United States show that the number of deaths from appendicitis is more than one half of that due to automobile accidents (21). In spite of many years' experience, it seems that there still are factors in treatment that can be bettered. One of the factors which contributes to the high rate of mortality is failure, in a certain group of cases, to recognize the presence of thrombophlebitis of the appendicular vein. The occurrence of this complication so alters the diagnostic, pathological, prognostic, and therapeutic features, that there may be justification for placing appendicitis, thus complicated, in a category of its own.

In this paper a survey of this type of appendicitis will be attempted together with the operative treatment thus far practiced. A composite picture of the clinical history of suspected thrombophlebitis of the appendicular vein will be given and an operative procedure will be suggested by means of which the process may be localized. Finally, a series of illustrative cases which have occurred in the last 10 years will be cited. These cases were drawn from several Newark (N. J.) hospitals and will serve to show the complete picture in specific instances.

PATHOLOGICAL CONCEPTION OF THROMBOPHLEBITIS COMPLICATING APPENDICITIS

The formation of a clot in a vein is most frequently a protective reaction against the spread of an infectious agent which reaches its radicles. The infected clot is formed in the lumen of the vein in an attempt to prevent immediate regional spread of infection or the later development of infection of the blood stream. If the virulence of the micro-organ-

isms is such as to cause progressive enlargement of the thrombus in the general direction of the heart, the result is the formation of an infected clot in a larger vein. Small pieces of such a clot may become detached and, in this way, an infected embolus is set free in the venous blood, the point where the embolus lodges depends upon where it was formed. Thus, in infections involving the intestines the liver receives the embolus by way of the portal vein, while an infected embolus arising in the head or extremities is filtered out by the lungs. When such an embolus comes to rest it causes a local tissue reaction which, in turn, is manifested clinically, by a sudden rise of temperature and a chill.

The micro-organisms against which the body has the poorest protective mechanism are certain types of streptococci. They seem easily to penetrate local protective barriers and quickly gain entrance into the venous radicles. A chill may occur as a complication of any infective disease process, but more especially those caused by streptococci. For example, in acute mastoiditis a chill and rise in temperature indicate that the infection has spread to the lateral sinus, resulting in a thrombus. In order to forestall later emboli, surgeons ligate the jugular vein on the corresponding side.

A similar process is found in certain cases of acute appendicitis in which micro-organisms reach the venous blood stream and thrombophlebitis of the appendicular vein results. Such a condition is usually due to a rapid gangrenous process caused by infections in which the streptococcus predominates. The micro-organism probably causes gangrene by an overwhelming infection and by affecting the veins of the appendix. Once the venules are involved, a protective barrier against further spread is established by the formation of an infected thrombus which stops the venous drainage of the part and hastens gangrene (17).

Submitted in partial fulfillment of the requirements for the degree of doctor of medical science at New York University

Whatever the mechanism may be which produces the thrombus, it does form in certain acutely inflamed appendices where there is rapid death of the part and in which the infection quickly reaches the venous radicles provoking the formation of a protective thrombus. Should a small portion of this clot break off, it is apt to lodge in the liver. In these circumstances a chill sets in, and a liver abscess eventually follows. No doubt there are many cases of acute appendicitis with septic thrombi in the appendicial vein that are unsuspected, and in which ligation of the mesentery during the removal of the appendix localizes the thrombus.

In a certain number of cases, however, a telltale pre-operative or postoperative chill gives warning of an existing thrombus and points to further procedures which should be attempted in order to stop any further septic emboli from being thrown off. Should the process progress unhindered, it may take one of two forms. More emboli may reach the liver, causing localized multiple septic areas and leaving the portal system comparatively free except for the small radicles about the appendix from which the trouble started. Or there may be marked inflammation of parts of the portal system, pylephlebitis, with massive purulent thrombi involving the ileocolic and right colic veins and liver involvement as well. Much of the literature on this subject deals with such cases or cases encountered at necropsy.

The first description of a case of appendicitis followed by pylephlebitis and liver abscesses is attributed by Loisson to Waller in 1846. Other occasional reports occurred sporadically over the next half century. Such articles were based entirely on the description of necropsy findings. In 1900, however, Deaver wrote, "The pylephlebitis is sometimes of the mild or non-infectious variety; frequently, however, the process is infectious, the thrombus becomes purulent, and leads first to abscess of the liver and subsequently to general infection with pyemia." He cites the cases of several patients who developed liver abscesses and in each of whom there was a history of repeated chills. Later he stated, "Chills are a rather uncommon occurrence in

appendicitis, yet if at the onset of the attack they occur in rapid succession, and are accompanied by temperature, they indicate a rapidly developing gangrene of the appendix. Chills occurring on the second or third day of the attack and associated with high fever usually indicate the development of metastatic or embolic abscesses." Kelly, writing 5 years later said: "Chills are exceptional in cases of simple diffuse inflammation, but are not rare with severe lesions. Of the patients with acute appendicitis not associated with abscess or general peritonitis admitted to Johns Hopkins hospitals, 15 per cent of them gave a history of chills, and in all of these, with the exception of two, the appendix was gangrenous, perforated, or distended with pus. Repeated chills occurring later in the course of the malady generally indicate a dissemination of the pyemic process." Thirty years ago, it would appear that these surgeons had practically recognized the disease entity of which we speak. They associated the condition with a gangrenous appendix in which dissemination of the purulent process into the portal system had taken place.

Individual case reports of liver abscesses following acute appendicitis and complicated by chills were cited by Bletchly, Bidwell, Brogden, and Cantab. Gerster, in 1903, suggested opening and draining the portal vein when it was found to contain a septic thrombus secondary to acute appendicitis. This procedure was the first operative interference to be suggested. It proved to be impracticable, however, because if the process extends this far, death is inevitable. Wilms, in 1909, cited the first case successfully treated by ligation of the venous radicles of the portal system. He stated, "On the second day a severe chill with high temperature occurred; three chills took place on the third day, and one on the fourth. Two hours after the last chill a second operation was performed. Upon exposure of the ileocecal region, the finger was introduced behind the ascending colon, thus freeing the beginning of the large intestines and the end of the ileum from the posterior parietes. After division of the posterior leaf of the mesentery into an oblique line between the ascending colon and the lower ileum, the

Fig 2 Thrombus in vein of mesentery. The thrombus is lamellated in one place and purulent elsewhere (Hematoxylin and eosin stain $\times 250$ —Thalhimer)

vessels could be recognized. Two small arteries which were particularly prominent were isolated, to guard against their being included in the subsequent ligation. Two mass ligatures sufficed to tie off all the veins in this locality. No subsequent chill occurred. The patient made a smooth and uneventful recovery." Sprengel, in 1911, reported a similar case in which a gangrenous appendix was removed and chills developed on the eighth day after operation. With Wilms' success in mind, secondary ligation was attempted 4 days later, after two more chills had occurred. This operation was technically more difficult because a localized adhesive peritonitis was found binding the ileocecal region to the retroperitoneal tissues; ligation, however, was finally accomplished. The patient died 3 weeks after the second operation, having had frequent rigors in the interval. Necropsy revealed, in addition to a localized focus of infection in the right iliac fossa, pyelephlebitis of the superior and inferior mesenteric veins. The liver contained multiple abscesses of varying sizes. In the 1911 volume of *Progressive Medicine* (25) this statement occurs: "Pylephlebitis occurring as a sequel of appendicitis has attracted attention for the past 20 years or more. For

tunately, its occurrence in the vast number of acute inflammations is rare. The mortality is very high. Symptoms pointing to its presence usually begin some time after operation, generally during the second or third week.

The outlook for cure of this condition by operation is, naturally, not brilliant for by the time that the first chill and high temperature indicate the presence of this condition the entire portal system may be hopelessly involved. Nevertheless in so hopeless a condition it seems fair to afford a patient the chance that operation offers for even if only a majority of the infecting thrombi can be disposed of it is conceivable that the system may be sufficiently relieved thereby to cope successfully with the remainder.

Braun, following Wilms' technique, tried ligation of the ileocolic vein unsuccessfully. Later, in 1913, he reported two successful cases. Neuhof experimented on dogs by ligating the portal vein, having in mind its possible application in the treatment of suppurative pyelephlebitis. He found that complete ligation is immediately fatal, and advocated ligation of individual branches at different times to allow a collateral circulation to form. He

concluded that, in view of the inevitable fatality of suppurative pylephlebitis, such a radical procedure should nevertheless be attempted and if done in steps the ligation would not kill the patient. Eight years later Christopher recorded the case of a patient in whom the symptoms and signs simulated lung abscess as indicated by chills, sweating, and general prostration apparently arising from changes within the chest; there were no localizing abdominal symptoms. After unsuccessful attempts at treatment of the suspected lesion in the chest, death occurred, and necropsy revealed multiple abscesses in the liver arising as a result of a retrocecal gangrenous appendix with pylephlebitis.

In 1924 Thalhimer reviewed the subject and reported 4 cases which he had observed. His paper, although of great importance, has received scant attention. He attempted to show that this grave clinical entity is overlooked by many surgeons. He drew a complete picture of the condition and laid particular emphasis on pre-operative chills as important in selecting operative procedures to check the spread of pylephlebitis. He advocated inspection of the veins leading away from any necrotic appendix, and, if any thrombi were found, ligation of the veins above the thrombus at the ileocecal junction and around the caput coli. In 1926 Colp (10) again drew attention to the subject and cited 3 cases in which patients were treated by high ligation of the portal or superior mesenteric veins. He concluded that high portal ligation was of no avail as the condition, if it had progressed that far, was hopeless. It is interesting to note that all of these patients survived the immediate effects of the portal interruption, but finally died as a result of liver abscesses.

INCIDENCE

Colp (11), in analyzing 2,841 cases of acute appendicitis, noted a chill as a symptom before operation in 68 per cent of all cases. Kelly and Hurdon found a history of chills in 15 per cent of cases. Fitz, in 1886, tabulated his necropsy findings in patients dead of acute appendicitis and found pylephlebitis in 11 cases of a total of 257 (4.7 per cent). Armstrong, in 1897, found a necropsy incidence of

5 per cent in 546 examinations. Gerster, however, found only 9 such cases with pylephlebitis occurring in 1,187 cases of acute appendicitis. Braun (3) reported 8 cases in 600 patients; Moschowitz, 7 cases in 1,529 patients; Gatch and Durman, 1 case in 262 patients, and Giertz 4 cases in 533 patients suffering from acute appendicitis. Petern, in a series of 1,340 necropsies in subjects dead of acute appendicitis, found liver abscesses in 5 per cent. In a recent study of 1,463 consecutive cases of all types of appendicitis, covering a 10 year period at the Newark City Hospital, there were 12 cases with 4 deaths. Other later statistics also show a lower incidence. This is due to earlier operative interference in acute appendicitis. With careful questioning, however, more patients with pre-operative chills will probably be found who never go into the later stages because the appendix with the thrombus is removed early.

PATHOLOGY

This type of fulminating appendicitis is attributed to the streptococcus. Thalhimer shows several pictures of bacteria in a vein thrombus (Figs. 1, 2) but he does not report any cultural studies to determine what type of micro-organism was present. The appendix is either acutely inflamed or gangrenous with a friable mesenteriolium in which the veins are thrombosed. Bier cites a case in which he found streptococci in the portal vein while the appendix showed but little inflammation. In the cases cited in this paper, however, the pathological changes in the appendix were advanced in every instance. If the septic thrombus is not removed or isolated when the appendix is removed, the thrombus extends upward. Sooner or later a small septic embolus may break off and, passing by way of the portal system, lodge in the liver, leaving the portal vein and most of its tributaries free. Thus, the ileocolic vein may be explored and found to bleed freely, containing no thrombus. Nevertheless, the radicles of the same vein may contain infected thrombi distal to the point of inspection and they may continue to be discharged into the liver unless the vein is ligated (Case 9). At times there may be a massive thrombus in the portal

system extending almost to the liver. In such a case, along the course of the vein, small localized abscesses may be formed due to perivenous infection. Until the liver is riddled with abscesses and its venous drainage has become thrombosed, the general systemic circulation may remain free of bacteria. Positive blood cultures are rare, as are lung abscesses secondary to liver abscesses. Empyema of the right chest by direct extension from a liver abscess is more common. There are some cases of jaundice due to liver destruction. Often a subicteric tinge is present. This change usually occurs later in the progress of this disease.

Another possible course for the infection to travel is through the lymph channels that lead to the liver, diaphragm, and subhepatic spaces. This avenue is probably more important in producing perihepatic and subdiaphragmatic abscesses. Most investigators, however, place little stress on the part played by the lymphatic channels or do not consider them at all.

Changes in the peritoneum vary with the stage of infection. In an advanced case of pyelephlebitis with massive clotting in the portal system there is usually an adhesive inflammatory process with edema of retroperitoneal tissues and regional lymph nodes. In other equally severe cases, on the contrary, the peritoneum may appear to be only slightly involved.

Sonnenburg believes that in all acutely inflamed appendices there are thrombosed venous radicles but that the virulence of the infecting micro-organisms is not sufficient to overcome local resistance and the affected radicles are removed early enough in most cases to preclude further development.

SYMPTOMATOLOGY

The patient usually gives a clinical history indicative of acute appendicitis. However, in addition, careful questioning is apt to elicit history of a chill which may have seemed so unimportant to the patient as to pass unnoticed. Even when a chill has occurred, the patient often attributes it to some condition other than that of his immediate illness. The thermal reaction of the body is similar to that

caused by the streptococcus elsewhere. Usually, even at the outset, the high elevation of the temperature is in strong contradistinction to that of other types of acute appendicitis in which severe local disease of the appendix may cause less than a degree of fever. Another important clinical observation is that these patients, as a rule, are more severely prostrated than in the usual type of acute appendicitis.

DIFFERENTIAL DIAGNOSIS

The most common condition to be confused with this disease is kidney infection or ureteral block on the right side. In this latter condition a chill may occur, but while the kidney region, or right flank, may be tender, the signs of acute intra abdominal inflammation are absent. Suspicion of early pneumonia with chill, prostration, and occasionally reflex abdominal muscle spasm may be entertained, and the diagnosis between the two may be difficult, although in acute appendicitis the lower right quadrant signs are usually easily detected early in the disease. If the patient is seen late the picture may be confusing because some of the signs may then have shifted to the upper right quadrant. In such circumstances liver or gall bladder disease or a subdiaphragmatic or liver abscess of different etiology may have to be excluded. Other possible confusing conditions that should be mentioned are right sided pelvic inflammatory disease, acute gastro-intestinal disturbances with chills, and early deep phlebitis of the right lower extremity.

In spite of the foregoing evidence accumulated over a period of years, some clinicians still believe that a chill associated with symptoms suggestive of appendicitis does not point to appendiceal inflammation with thrombus formation and secondary embolism. Some still deny that such an entity exists and attempt to explain the sequence of events by some process other than that of acute appendicitis. It has even been said that a chill excludes the diagnosis of appendicitis. The burden of proof rests on the exclusion of acute appendicitis. It is important to emphasize this point so that the diagnosis may be made early. If there is delay if only for a few hours,

the damage may have become irreparable, especially, if, in the interim, septic emboli have lodged in the liver. It is possible that the liver can overcome a small dose of infected material, but a large dose is almost certain ultimately to cause death in spite of all therapeutic measures.

SURGICAL TREATMENT

Operation is best performed at the earliest possible moment. Spinal anesthesia is the anesthetic of choice, if the patient's condition will allow its use. With this type of anesthetic the viscera are quiet and the abdominal muscles relaxed, permitting a maximum of exploratory possibilities. The right rectus incision with the upper end opposite the umbilicus seems the incision of choice as giving the maximum exposure for exploration. By placing the patient slightly on the left side with a sandbag under the right loin the intestines tend to fall away from the right gutter. After the abdomen is opened the small intestines are packed away with hot sponges to obtain a clear view of the ileocecal junction. The small tributaries of the ileocecal vein may be seen beginning to form a common trunk which runs in the posterior parietal peritoneum in a line drawn from the ileocecal valve to a point in the midline midway between the umbilicus and the xiphoid process. The vein does not continue the whole length of this imaginary line as it empties into the right colic vein just above the umbilicus. It will be found to join the right colic vein just below the third portion of the duodenum. Care should be taken, if there be any question as to anatomical location, to identify this point of juncture and to interrupt the venous return distal to this point, i.e., to ligate the ileocolic vein only. Lying to its medial side throughout its course is the ileocolic artery. The vein thus identified is gently palpated for the presence of a thrombus which, if present, stands out as a stiff, cord-like structure. An attempt is made to follow the vein above the thrombus to a point where the vein has no clot in its lumen. Even though no thrombus be found, the vein should be isolated, ligated, and then severed, the point of ligation being as close to the right colic vein as possible. Walcker (Fig. 3) has

Fig. 3. Anomalies of the venous drainage of the ileocecal angle (From Walcker, loc cit)

pointed out the anomalies of the veins draining the ileocecal region. With these anomalies in mind, a low ligation of the ileocolic vein might fail to prevent further spread of the process into the liver. However, ligation of the ileocolic vein just before it empties into the right colic vein will avoid not including the whole venous drainage of this area even though it should be anomalous. This point of ligation is about 4 inches in the above mentioned line from the ileocecal valve. There is no fear of causing gangrene of the intestine by this procedure. In a certain number of cases the circulation is already obstructed by the thrombus in these veins, and in no case has gangrene been observed. Colp (10) cites several cases of ligation of the portal vein itself without ensuing gangrene. This part of the operation should be performed before the appendix is removed.

At times the process may be so early as to make opening the retroperitoneal space unnecessary. When the thrombus is limited to one small nodule the appendiceal vein may be dissected high behind the ileocecal junction and ligated at this point. Such a procedure has been done in certain cases in which there was no chill, but in which the appendiceal veins were found thrombosed at operation. It was also done in several other early cases in this series in which a chill had occurred but the thrombus was found only in the appendiceal veins. In the late case with several pre operative chills such an operation is usually insufficient and only leads to trouble later as the process has advanced beyond the point of attack.

REPORT OF CASES

Twenty four cases are here presented. For the purpose of accuracy they have been divided into a proved and a presumptive group, although they are all thought to be illustrative of the disease entity under discussion. In these 24 cases the history, presence of a chill or chills, together with definite operative findings of acute appendicitis, all fit into one similar clinical picture. Only proved examples of thrombophlebitis are included in the group to be listed first. In the presumptive group have been listed those cases in which either no thrombus was found or noted in the operative record and those cases in which a thrombus could not be identified because of existing pathology. In several of these cases no autopsy could be obtained to prove the diagnosis.

PROVED CASES

CASE 1. E. S. admitted to Newark City Hospital January 28, 1930, white male, 32 years old with history of dull continuous pain in the right lower quadrant for the past 2 weeks. Patient had several acute exacerbations of pain. He vomited once about a week ago. Pain has been more severe in the past few days. He has had chilly sensations on several occasions. Temperature on admission was 100.4 degrees, pulse 100, respirations 22. Examination revealed extreme tenderness in the right lower quadrant. Patient did not look extremely ill. Patient was operated upon 2 hours after admission. The abdomen was opened through a McBurney incision. The appendix was gangrenous throughout the mesenteric vein was thrombosed. The meso-

appendix was ligated high and the stump was inverted. Two roll rubber drains were inserted through a stab wound. Patient's course was without note except for an acute bronchitis. He left the hospital on the twentieth day.

CASE 2. C. G., admitted to Presbyterian Hospital December 31, 1930, a 15 year old schoolgirl gave a history of abdominal pain for past 3 weeks. Chills, high fever, increase in temperature and pain in right lower quadrant, nausea and vomiting. An icteric tinge to the sclera was noted. High color to urine. She was brought to the hospital for observation and diagnosis. Temperature on admission 105.0 degrees, pulse 130, respirations 34. Blood count 20,000 with 86 per cent polymorphonuclears. Patient on admission was toxic, somewhat dehydrated. Examination showed moderate tenderness in right lower quadrant with suggestion of a mass the size of an egg and marked rigidity in right upper quadrant with some tenderness over the liver. Operation was performed January 1, one day after admission with pre operative diagnosis of retrocecal appendiceal abscess with pyelphlebitis. The abdomen was opened through a McBurney incision. A large mass was found surrounding the appendix. The appendix was removed. Two roll rubber drains were placed in the area of the appendix, one Penrose drain in pelvis. The wound was closed in layers. Temperature remained high. On first postoperative day she had a chill followed by one or more chills on the second, third, fourth, fifth, ninth, eleventh, thirteenth, seventeenth, and eighteenth days. Temperature was spiking in character and hectic. Patient was transfused on the ninth day after operation. She continued to complain of pain in the right upper quadrant. In spite of supportive measures and intravenous fluids course continued downhill with vomiting and abdominal distention. Death occurred on the twenty second day after operation. Autopsy revealed acute spreading peritonitis secondary to a gangrenous appendix, pyelphlebitis of mesenteric and portal vessels, multiple liver abscesses, toxic nephritis and myocarditis and terminal pulmonary edema.

CASE 3. L. R. admitted to Newark City Hospital October 4, 1931, white male, 28 years old, complaining of cramps and pain in the stomach and in the lower left quadrant for 2 days. Day before admission he took castor oil. On day of admission he had a chill and a high fever. On admission his temperature was 104.3 degrees, pulse 88, respirations 22. Operation was performed 1 hour after admission through a right rectus incision. The abdomen showed rigidity in both quadrants with deep and rebound tenderness. No masses were palpable. Rectal examination revealed a mass high just to the right of the midline. It was a curving putty like mass the size of a pencil. It was tender. Diagnosis was made of acute gangrenous appendicitis with pyelphlebitis. The peritoneum was opened and revealed free red tinged milky fluid. The appendix was found black and ruptured dipping over the brim of the

pelvis, with thrombosis of the appendicular vessels. The appendix was removed. A thrombosed mesentery was dissected out high above thrombus. Two rolled rubber drains were inserted through a stab wound. Sliver drains under fascia. Patient made a good and uneventful postoperative recovery except for superficial wound infection. He was discharged from the hospital on the twenty-fifth day after operation.

CASE 4. H. H., admitted to the Presbyterian Hospital December 30, 1931, white male, 13 years old; with a history of pain in the stomach for 1 day followed by vomiting and localization of the pain around the umbilicus. He had had one previous attack 2 months ago. Diagnosis of appendicitis was at first ruled out, but in 24 hours the symptoms again recurred and the patient was admitted to the hospital. Ice cap was placed on the abdomen and patient was kept on liquids. On the first day after admission the patient had a severe shaking chill lasting 20 minutes. A consultation was called and an immediate operation was then decided upon. White blood count before operation was 11,500 with 88 per cent polymorphonuclears. A diagnosis of acute gangrenous appendicitis with thrombophlebitis was made. Operation was performed through a lower right rectus incision. Appendix was kinked at its mid-point, the distal half being gangrenous. There was a definite thrombophlebitis of the appendicular vein. Appendicular vein was ligated high above the thrombus, and the appendix was removed in the usual manner. The stump was buried. One Penrose drain was brought through a stab wound. The wound was closed in layers. Patient's course was not stormy. Temperature gradually fell. Large quantities of intravenous fluids were given for 5 days. On the twelfth day after operation there was an unexplained rise in temperature to 101° degrees. Patient, however, looked so well that he was discharged from the hospital 2 days later on the fourteenth day after operation.

CASE 5. R. B., admitted to Newark City Hospital January 8, 1933, white male, age 39 years; with a history of being well until the day of admission when he began to have pain around the umbilical region which was sharp and cramplike. It then descended to the right lower quadrant and he began to vomit. He began to feel feverish and came to the hospital, he had a real chattering chill which lasted for several minutes. On admission he had a temperature of 105° degrees, pulse, 120, respirations, 28. He complained of pain in the right lower quadrant and on examination he was found to have moderate rigidity and rebound tenderness over McBurney's area. No masses were palpable. Diagnosis of acute gangrenous appendicitis with thrombophlebitis of the appendicular vein was made. He was operated upon 4 hours after admission. His abdomen was opened through a right rectus incision. The appendix was found swollen, edematous, injected, and friable. The veins of the appendix were noted to be everywhere thrombosed. The appendicular vein was followed up the mesentery

until it could be ligated above the palpable thrombus. It was then cut and ligated at both ends. The appendix was removed in the usual manner. The stump was buried. The abdomen was closed in layers; no drainage. Patient's temperature dropped from 105° to 100° degrees within 12 hours. Temperature never again went above 100° degrees, and he made a successful recovery unhampered, to be discharged from the hospital on the tenth day after operation.

CASE 6. T. G., admitted to Presbyterian Hospital February 12, 1934; white male, 50 years of age; complained of onset on previous day of slight diarrhea and pain across lower abdomen, with a slight nausea and some vomiting. The pains persisted in the right lower quadrant. The preceding evening he had had several chills followed by a high temperature. He gave no history of previous attacks. Examination showed abdomen to be distended with gas, tenderness and spasticity in the right lower quadrant with rebound tenderness, but no masses. Temperature on admission was 102.6 degrees; pulse, 90. Leucocytes numbered 12,000 with 90 per cent polymorphonuclears. A diagnosis was made of gangrenous appendicitis with pylephlebitis. Operation was done 2 hours after admission through a right rectus incision. A gangrenous appendix with a thrombosed mesenteric vein was dissected high and the vein was ligated above the thrombus. Two Penrose drains were placed through stab wound, one into the pelvis and one into the right gutter. He was given intravenous fluids after operation. Temperature declined uneventfully. Patient made a smooth recovery. He was discharged on the twentieth day after operation.

CASE 7. E. B., admitted to St. James Hospital February 23, 1934, white male, 20 years old; complained of onset of pain across the lower abdomen 3 days previous. The pain was sharp and continuous. He vomited several times. Two days ago he was given a laxative and since then he has had diarrhea. Pain continued to be severe up to admission. He began to feel feverish the day of admission. Two days before admission he also had a shaking chill which lasted about 10 minutes. When admitted to the hospital his temperature was 102.6 degrees, pulse, 102, respirations, 24. He had tenderness and rigidity over the lower abdomen, more in the right lower quadrant. He complained of severe abdominal pain. The white blood count was 28,750 with 87 per cent polymorphonuclears. The urine showed 2 plus albumin. A diagnosis was made of acute gangrenous appendicitis with thrombosis of the appendicular vein. Operation was performed through a McBurney incision, revealing a small amount of clear serous fluid. The appendix, stiff and bound in adhesions from the omentum and the terminal ileum, lay at the pelvic brim. The adhesions were freed. When the mesoappendix was separated down to its base, a hard, bluish, tube-like structure which was the appendicular vein, thrombosed throughout, was found. The appendix was clamped, tied off, am-

puted and the stump was inverted. Because of the patient's condition the thrombosed appendiceal vein was not dissected up behind the ileocecal valve but a ligature was placed above the thrombus. No intra abdominal drainage was used. Silver drain was placed under the fascia. Patient had diarrhea for 1 week after operation. He was given large quantities of fluids. On the fourth day he had a severe shaking chill for 10 minutes and his temperature rose to 104.6 degrees. Temperature fell again, immediately after the chill. Temperature gradually returned to normal. On the twelfth day the diarrhea abated and the patient's condition seemed good except that he complained of abdominal pain daily. The temperature remained flat for 4 days more until the seventeenth day when he began to have a temperature rise with an increase of diarrhea. The abdomen was soft but he complained of abdominal pain. Blood count showed 31,250 leucocytes with 85 per cent polymorphonuclears. Stool examination for parasites was negative. He still had two plus albumin in the urine with a few pus cells. Diarrhea was not controlled by bismuth. However, after reaching a peak of 102.0 degrees on the twenty-second day temperature gradually fell to normal on the twenty-sixth day. From then on he continued to be free of fever and symptomless until his discharge from the hospital on the thirtieth day after operation.

CASE 8. F. A. admitted to Newark City Hospital June 5, 1934, white female aged 24 years, complained of onset of abdominal pain on the morning of the day before admission. There had been no attacks similar to the present condition. Onset of pain was followed by nausea and vomiting in several hours. Pain was of a sharp and intense character. It soon localized in the right lower quadrant. She had a chill and noticed that she had some fever. Pain then became of sharp character radiating to the upper right quadrant and accompanied by pain in the shoulder. She vomited several times the night before admission. She was thought to be about 8½ months pregnant. A provisional admission diagnosis was made of acute suppurative appendicitis complicating pregnancy. On physical examination she was found to be dehydrated and dyspneic with slight cyanosis. Temperature was 101.6 degrees, pulse, 131; respirations 40. The abdomen was found symmetrically enlarged, the uterus extending midway between the umbilicus and the xiphoid. Position of the child was determined as left occiput anterior. The child was alive with a strong regular heartbeat of 134 a minute. There was direct and rebound tenderness over the entire abdomen especially the right lower quadrant. Moderate rigidity was found all over the right side of the abdomen. White blood count was 17,400 with 88 per cent polymorphonuclears. A diagnosis of retrocecal gangrenous appendicitis with pyelephlebitis was made. She was given 1,000 cubic centimeters of saline solution before operation. Operation was done through a high McBurney incision. When the

peritoneal cavity was opened free purulent fluid with a strong *Bacillus coli* odor welled into the wound. The uterus which encroached on the medial side of the wound was walled off with a warm sponge. The cecum was found lying high out of the right lower quadrant just in the upper quadrant. The appendix was gangrenous, bound down and in a retrocecal position. A large fecolith was found lying free in the abdomen. An attempt to invert the stump was not entirely successful due to the position of the appendix. The appendiceal vein was ligated high above a thrombosed mesentery. Two Penrose drains were placed in the right gutter through a stab wound. Several silver drains were placed under the fascia. Because of the pregnancy a duodenal suction drainage as a prophylaxis against expected abdominal distention was started immediately. She was given fluids by vein and under the skin. General postoperative course was not so stormy as might have been expected. Distention was quite easily controlled. On the sixth day she showed slight vaginal spotting with no pain. This was the only sign of possible interruption of the pregnancy on this admission. The wound drained freely of thick foul *Bacillus coli* pus; the drainage gradually diminishing to a scant spotting at the time of her discharge from the hospital. She was allowed out of bed on the fourteenth day and was allowed to go home on the eighteenth day with the advice to go home and remain in bed. However, 2 days later she was admitted to the obstetrical ward in early hard labor. She was delivered 9 hours later of a living normal child. Following the delivery of the placenta there was a moderate quantity of foul smelling purulent material expressed from the vagina. A culture of this material and a direct smear both showed a gram positive diplococcus. The puerperium was uneventful except for a rise in temperature to 100.4 degrees on the third day. Blood Wassermann was negative. She again left the hospital on the tenth day postpartum.

CASE 9. D. D. admitted February 2, 1935 to Newark City Hospital, white male aged 30 years with a history of developing continuous sharp pain about the umbilicus on the day before admission with nausea and vomiting. The pain shifted to the right lower quadrant. There was no history of any previous attacks. On the day of admission patient had a severe shaking chill which lasted about 10 minutes. Temperature on admission was 100.4 degrees, pulse 100, respirations 26. He had direct and rebound tenderness over McBurney's point with some rigidity. White blood count was 13,200 with 89 per cent polymorphonuclears. Diagnosis was made of acute gangrenous appendicitis with thrombophlebitis and operation was performed 4 hours after admission. Because a mass was thought palpable in the right lower quadrant a McBurney incision was made revealing marked localized adhesive and purulent peritonitis surrounding a gangrenous appendix. Although pyelephlebitis had been suspected no extensive operation was performed be-

cause of fear of spreading the virulent process throughout the abdomen. The appendicial vein was, however, exposed as high as possible and ligated. One Penrose drain was placed through a stab wound. After operation he had a cough, productive of thick, tenacious mucus. It seemed to clear up within 3 or 4 days with medications. On the fifth day he had a slight chill with temperature of 104.2 degrees, and another on the tenth day. He was given large quantities of fluids by hypodermoclysis. He continued to vomit in spite of duodenal suction drainage through a Levine tube. His condition seemed poor. He began to cough and expectorate repeatedly. He vomited intermittently. There was but little drainage from the stab wound. The wound was healing well and seemed clean. This general picture continued until the third week when he seemed to be gradually improving. On the twentieth day after operation he had a severe shaking chill with a temperature elevation to 105.0 degrees. The next day he received a transfusion of 500 cubic centimeters of blood. He seemed much weaker. His vomiting and abdominal pain returned. He again had another chill 2 days later. Secondary exploratory operation was done on the twenty-fourth day through a long right rectus incision, revealing free, thin reddish fluid in the abdomen. No pocket of pus was encountered. All of the mesenteric glands were enlarged. The pancreas and liver were enlarged. On the dome of the right lobe of the liver, 3 hard nodules were palpable. The ileocolic vessels were explored and opened. They bled freely showing there was no massive thrombosis. Diagnosis was made of multiple liver abscesses. He received a transfusion the next day together with intravenous fluids. He continued to vomit. A Levine tube was again inserted. He received another transfusion on March second, and on the same day 6 hours after the transfusion he had another severe chill, followed by another one on the next day. Successive blood cultures taken at this time were negative. X-rays of the chest were negative until April 6, when the dome of the right diaphragm seemed raised. He had been having chills on and off every few days with few other signs in the abdomen except right upper quadrant tenderness. On April 9 he was taken to the operating room again and the twelfth rib resected in the midaxillary line in order to drain a subphrenic abscess and a contiguous liver abscess. Blood cultures remained negative throughout. He continued to have chills. His condition did not improve. He continued to appear weak and listless in spite of continued transfusions and other supportive measures. He vomited frequently. He went downhill gradually and on April 24, he died, 81 days after admission. At autopsy there was found a slight icteric tinge to the scleræ. Otherwise, the autopsy was essentially negative except for the abdomen. The lower part of the abdomen contained straw colored fluid. There was a purulent plastic exudate of the lower abdomen. There were fresh adhesions of the superior surface of the liver to the diaphragm.

Small amount of purulent fluid was found over the right lobe of the liver. There was extensive plugging of the portal vein at the hilus of the liver with a purulent organized thrombus. The left lobe of the liver was practically free of abscesses. The right lobe of the liver was riddled with discrete confluent abscesses which contained creamy, thick, yellow, foul pus.

CASE 10 L. B., admitted to Presbyterian Hospital June 2, 1935; white male, 39 years old; with a history of having chills and fever every night for the past week but no symptoms during the day. Patient went to work during the day, at night he felt chilly and had a chill. Several nights previous he vomited. He had had no pain to speak of since the beginning of his illness. On admission to the hospital he had a temperature of 101.4 degrees; pulse, 88; respirations, 22. White blood count was 10,000 with 80 per cent polymorphonuclears. On examination he did not seem acutely ill. He was slightly dehydrated. There was some tenderness in the right lower quadrant with moderated rigidity of the right rectus muscle. A kidney infection on the right side was considered as the probable diagnosis for the first 24 hours in the hospital because a urinary examination erroneously reported the presence of a large number of leucocytes. After this possibility was ruled out by subsequent urinary examinations, operation was decided upon to determine whether the pathology arose from the appendicial vein as was then suspected. Operation was done with spinal anesthesia through a right rectus incision 5 inches long. An appendix gangrenous at its tip was found. The mesentery of the appendix was edematous and contained hard, cord-like veins. Palpation of the ascending ileocolic leaf of the mesentery revealed an edematous, ecchymotic mass extending upward, which was identified as the ileocolic vein. The mesentery of the ascending colon was separated by blunt dissection and the ileocolic vein was ligated high, about 6 inches above the ileocecal valve. The appendix was removed, the stump inverted, and the abdomen was closed in layers. A silver drain was placed under fascia. At the time of operation his temperature was 104.0 degrees. Following the operation his temperature continued to be high. For 43 days he continued to have a spiking temperature going to 106.0 and 107.0 degrees following rapid and frequent chills which occurred sometimes twice a day. He received intravenous fluids and multiple small blood transfusions. The abdominal wound was well healed. His abdomen did not become distended. His chills later became more violent in character, some lasting as long as 55 minutes. He died 44 days after admission. Autopsy revealed the abdominal cavity to contain a considerable amount of clear fluid, about 4 liters. There were a large number of adhesions between the intestines and the gall bladder. In addition, there were pus pockets containing thick greenish pus on the right side of the abdomen. The mesentery contained a large amount of pus in areas extending along the mesen-

teric vessels. There were abscesses along the portal vein. The liver was enlarged, congested, and the left lobe was practically gone, being replaced by a large abscess containing thick green pus. The right lobe contained small abscesses scattered throughout, apparently along the veins. The spleen was tremendously enlarged, dark and soft.

CASE 11. W. B. admitted to Presbyterian Hospital August 23, 1935, white male 43 years old, complained of sudden pain in the epigastrium beginning the day of admission. Pain soon descended to the right lower quadrant. Nausea followed and had persisted to admission. About an hour before admission he had a chill. Examination on admission showed a well developed adult male apparently acutely ill and suffering pain in the lower abdomen. There was direct and rebound tenderness over McBurney's point. Temperature was 101.4 degrees pulse 96. A diagnosis of gangrenous appendicitis with pylephlebitis was made. Operation was done within 1 hour after admission through a lower right rectus incision. The appendix was brought into the wound. The mesoappendix was ligated high above a thrombosed appendicular vein. The appendix was removed in the usual manner, no intra abdominal drainage. Silver drain was inserted under the fascia. Patient was given intravenous fluids and sedatives. Postoperative course was uneventful. Was discharged on the twelfth day after operation.

CASE 12. C. M. admitted to Newark City Hospital October 13, 1935, colored male 32 years old, was placed on the medical service with a diagnosis of pyelitis. Past history was essentially negative. Present history states that he was out drinking 10 days ago and came home drunk. The next day while at work he had some slight abdominal pain which cleared up after an hour or so. He continued at his work. After leaving work he went to bed as he did not feel well. That night his doctor ordered salts and cream of tartar for the patient. Two days after the onset and soon after he took the cathartic the patient felt nauseated and vomited once. He has also vomited once since then. For the past 8 days he has been having chills about 2 a day. He has been feeling feverish all this week. He now has some pain and tenderness in the right upper quadrant. On admission his temperature was 103.0 degrees pulse 88 respirations 24. White blood count was 8,900 with 82 per cent polymorphonuclears. The urine showed a specific gravity of 1.022 with trace of albumin. Another specimen was positive for bile. The sclerae looked slightly jaundiced. The abdomen was distended but no masses were palpable. There was tenderness over the costal border in the right upper quadrant. Diagnosis while on the medical service was possible pyelitis, possible septicemia and possible typhoid fever. Two days after admission the white blood count had risen to 13,200 with 84 per cent polymorphonuclears. Four days after admission the medical service made a diagnosis of sub-diaphragmatic pleurisy with abscessed liver, the etiology being (1) mesenteric thrombosis (2) pyle-

phlebitis from acute appendicitis (3) ruptured gastric ulcer. A surgical consultation was called and a diagnosis made of pylephlebitis secondary to acute appendicitis. He was transferred to the surgical ward and on October 18, 5 days after admission was operated upon. The abdomen was opened through a right rectus incision. The peritoneal cavity contained a moderate amount of free straw colored fluid. There was a great deal of edema of the mesentery and the mesenteric glands were palpable. There was a mass consisting of appendix and omentum in the right lower quadrant. The appendix was retrocecal. It was removed with the cautery and the stump was inverted with a purse string. One inch from the base of the appendix along the ileocolic vessels there was an abscess cavity containing foul smelling pus. One inch proximal to this point and parallel with it was another abscess cavity. The ileocolic vein was ligated 3 inches from the appendix and ileocecal angle. No thrombus was found at this point. Two drains were placed through a stab wound into the right gutter and abscess cavities. The wound was closed in layers. Patient was given large amounts of fluids after operation. He continued to have severe chills and temperature shooting up to 105.0 degrees. He went steadily downhill, dying 2 days after operation and 1 week after admission to the hospital. Autopsy revealed multiple liver abscesses, suppurative abscesses along the course of the ileocolic and portal vein with thrombosis of the portal vein at its entrance to the liver. There was marked liver destruction by abscess formation.

CASE 13. W. S., admitted to Newark City Hospital October 26, 1935, 15 year old white male, assigned to the Surgical Service with complaint of abdominal pain which had started 2 days previously and which had begun with cramps around the umbilicus. Patient had vomited nine times since the onset. The pain shifted to the right lower quadrant. There had been loss of appetite and the bowels had become irregular. On day of admission in the morning he had a chill. The day the pain began he took a strong cathartic and an enema. Temperature on admission was 103.6 degrees pulse 120 respirations 20. A diagnosis was made of a ruptured appendix. The abdomen was rigid throughout with direct and rebound tenderness more in the right lower quadrant. Patient was operated upon 4 hours after admission through a McBurney incision. The peritoneum was opened and revealed pus in the abdomen. A ruptured gangrenous appendix was found covered with omentum and fibrin. A thrombus could be palpated in the appendicular mesentery. The appendicular vein was ligated high above the thrombus. The appendix was removed and the stump inverted. Two Penrose drains were placed through a stab wound. The abdomen was closed in layers with clips in the skin. The postoperative course was uneventful except for profuse purulent drainage from the wound, the temperature dropping to normal after the first week.

CASE 14. H. S., white male, aged 63 years, was admitted to the Presbyterian Hospital on January 7, 1936, with a history of having had an attack of lower right quadrant pain 4 days before admission. He was nauseated and vomited. Two days after it started he took a cathartic. For the past 2 days the pain has been more severe and has remained in the right side. He has been unable to eat. There is no history of a chill. On admission he had a temperature of 102.4 degrees, pulse, 80, respirations, 28. He was dehydrated, not in any apparent acute distress at present or complaining of severe pain in the right side. Examination was essentially negative except for the abdomen which was soft except in the right side where there was direct and rebound tenderness and also a small palpable mass in the right lower quadrant. A pre-operative diagnosis was made of acute appendicitis with thrombophlebitis. Operation was performed through a lower right rectus incision 1 hour after admission, and revealed a gangrenous appendix which was perforated at its base. The appendix was removed and the stump was not inverted. The abdomen contained thick purulent fluid which was aspirated. Two Penrose drains were inserted and brought out through a stab wound. The wound was closed in layers, leaving one sliver drain under the fascia. The patient apparently made an uneventful recovery for the first 17 days. The wound drained a great deal of thick pus. On the eighteenth day one Penrose drain was removed and approximately 12 hours later he had a severe, shaking chill. He was apparently comfortable and without complaint until the chill occurred. The temperature rose to 102.0 degrees. Patient vomited after the chill. He had another chill that evening lasting 30 minutes with a temperature of 103.0 degrees. On the twenty-third day after operation another Penrose drain was removed, it was followed in 7 hours by another severe chill lasting 20 minutes. He complained of feeling chilly the next day and the following day he had another severe chill. The next 6 days he had successive chills with temperature rises up to 105.0 degrees. On February 8, 32 days after his appendectomy, he was again operated upon and a ligation of the ileocolic vein about 4 inches above the ileocecal valve was performed through a right rectus incision opposite the umbilicus. Duration of the operation was 45 minutes. Exploration of the abdominal cavity was not done. The ileocolic vein on section bled freely. For 2 days after the vein ligation the patient's temperature remained normal. On the third day after this operation he had three severe chills and until the date of his death, 45 days after the original operation, he had at least one chill and high temperature rise each day. Blood cultures on several occasions showed a growth of non-hemolytic streptococci. Autopsy showed a liver with one large abscess and several small abscesses, along the course of the portal vein there were small abscesses with a large thrombus almost filling the portal vein. The area of ligation was explored and distal to the point of ligation the

small veins were found thrombosed, but the intestine in this area was not affected by this interruption of the blood supply. There were multiple small abscesses also in the lungs.

CASE 15. W. T., white male, age 43 years, was admitted to St. Mary's Hospital, Orange, June 28, 1936, with a history of having been awakened from his sleep early on the morning of admission with severe abdominal discomfort. The pain was relieved after defecation only to return in several hours. The pain remained generalized in the abdomen most of the day. Toward evening it centered in the right lower quadrant. Just previous to admission patient had a shaking chill followed by another after admission. On admission patient's temperature was 102.0 degrees, pulse, 98, respirations, 20. Physical examination was essentially negative except for a moderately rigid abdomen with considerable rebound tenderness. The pre-operative diagnosis was acute appendicitis with thrombophlebitis. He was operated upon 5 hours after admission, by Dr. A. J. Ganley, through a McBurney incision. A gangrenous appendix was found. No free abdominal fluid was present. The appendix was removed, the mesentery of the appendix was ligated high, and the abdomen was closed without drainage, one sliver drain being placed under the fascia. The temperature fell to 100.0 degrees on the first day after operation and remained normal after the fourth day. He made a completely uneventful recovery except for catarrhal conjunctivitis, to be discharged from the hospital on the eleventh day after operation. Microscopic pathological examination report reads: "The mucosa of the appendix is necrotic and purulent. Scattered throughout the edematous walls are polymorphonuclears. On the external surface is noted fibrinopurulent exudate. The meso-appendix shows clots within the lumen of the blood vessels."

CASE 16. F. M., white female, age 40 years, was admitted to the Presbyterian Hospital on October 11, 1936, with a history of abdominal pain which has been generalized for the past 36 hours. She has felt nauseated but did not vomit until the day of admission. The morning of admission the pain localized in the lower right side and she had a severe, shaking chill which lasted several minutes. Examination on admission revealed tenderness and rigidity all over the lower abdomen with rebound tenderness on the right side. Temperature was 100.2 degrees; pulse, 100; respirations, 20. She was operated upon soon after admission through a lower right rectus incision, an acutely swollen appendix, which was gangrenous, was found. There was no free fluid in the peritoneal cavity. When the mesoappendix was separated practically no bleeding occurred. The veins in the mesoappendix were found thrombosed and were ligated high behind the ileocecal valve. Two Penrose drains were inserted through a stab wound; the incision was closed in layers. Large amounts of thick purulent fluid drained from the wounds. The patient made a continuous progressive recovery. Her temperature was normal on the eighth day after

operation. Pathological report on the appendix was acute gangrenous appendicitis with thrombophlebitis. She was discharged from the hospital on the twenty first day after operation. Drainage had stopped and her general condition was very good.

IRRESUMPTIVE CASES

CASE 1. A L, admitted to Newark City Hospital August 10 1927 white female aged 32 years complained of weakness for 5 days with pain in the back and general malaise. Three days ago she had a chill she felt feverish and began to have pain across the lower abdomen. The pain soon radiated more to the right side in both upper and lower quadrants. Several hours later she had a vomiting attack and has had several since then. Temperature on admission was 101.6 degrees pulse 120 respirations 44. Examination revealed that the abdomen was everywhere rigid, more on the right side with direct and rebound tenderness. No masses were noted. White blood count was 16,200 with 87 per cent polymorphonuclears. Diagnosis was made of an acute surgical abdomen with peritonitis secondary to an acute appendix. Operation was performed 4 hours after admission through a right rectus incision. Free purulent fluid was found in the region of the appendix which was thick and acutely inflamed. The appendix was removed. Two drains were inserted through a stab wound and 4 sliver drains under fascia. She made a good surgical recovery from the operation, but she developed a chest complication with a cough and an area of apparent consolidation at the right base. This cleared up slowly and she appeared to have an area of unresolved pneumonia. After prolonged rest in bed the right chest cleared and patient was discharged from the hospital on the forty fifth day after operation.

CASE 2. W E, admitted to Newark City Hospital October 12 1927 white male 10 years old with a history of generalized abdominal pain which radiated to the right lower quadrant, for 3 days. The pain has persisted he vomited and was given cathartic day after pain started. The next day he had a chill. He has had earaches for the past several weeks with discharging ears for several days. On admission the abdomen was very rigid board like with direct and rebound tenderness throughout. Temperature on admission was 101.0 degrees pulse 120 respirations 36. The white blood count was 12,600 with 86 per cent polymorphonuclears. Diagnosis was made of ruptured appendix with acute otitis media. Operation was performed 4 hours after admission through a right rectus incision. A moderate amount of free green purulent fluid was found. The appendix was gangrenous. The appendix was removed in the usual manner the stump burned and 2 Tenrose drains were inserted through a stab wound with sliver drains under the fascia. After operation the child continued to improve. The ear condition cleared up with irrigations. Patient made a smooth continuous recovery to be discharged on the twenty sixth day.

CASE 3. J F, admitted to Newark City Hospital January 2, 1929 white male 28 years old complained of pain and vomiting almost continuously for the past 2 days. Pain at first was generalized but now is confined to the right lower quadrant. Yesterday he had a profuse sweat followed by a 15 minute shaking chill. He has felt severely prostrated. Temperature on admission was 101.0 degrees, pulse 86 respirations 26. White blood count was 16,900 with 89 per cent polymorphonuclears. A diagnosis of acute gangrenous appendicitis with phlebitis was made. Examination revealed marked rigidity of the abdomen, extreme tenderness throughout but most marked in the right lower quadrant. Operation was done 2 hours after admission through a McBurney incision and revealed free fluid. The appendix was retrocecal and necrotic throughout. The terminal ileum and cecum surrounding the appendix also showed signs of healing necrosis with marked edema. The appendix was removed the stump inverted, and the mesoappendix ligated high. Two stab wound drains were used to the pelvis and one to the right gutter were used. Intravenous and subcutaneous fluids were given for the first 4 days. Foul thick pus exuded from the wound for 2 weeks. Patient's course was stormy, with frequent vomiting and hiccoughing and signs of localized peritonitis. Patient was discharged from the hospital on the nineteenth day after operation in good condition the wound being healed.

CASE 4. J J, admitted to Newark City Hospital, March 22 1930 white female 16 years old, complained of being seized with pain in the epigastrium. Two days before admission the pain became more severe and was accompanied by vomiting. The day before admission he had several chills. Examination showed a well developed well nourished girl acutely ill with general abdominal tenderness. Temperature on admission was 101.2 degrees pulse 122 respirations 20. The abdomen was rigid with rebound tenderness especially in the right lower quadrant. There were no masses and no obliteration of liver dullness. The diagnosis on admission was possible biliary colic with possible pancreatitis. Blood count was 8,000 with 81 per cent polymorphonuclears. The urine was negative. Patient was operated upon 8 hours after admission. A lower midline incision was made and revealed the peritoneal cavity full of buff colored pus. The appendix was removed after ligation of the base. Ileostomy was performed. Three roll rubber drains were placed in the abdomen. The postoperative course was stormy with the development of jaundice. On the second day the patient in spite of all measures developed considerable distention and vomiting due probably to peritonitis. There was profuse drainage from the wound on ninth day. Fecal drainage from wound developed and a definite fecal fistula was established. On the same day bleeding from the wound began clots of blood appeared from under dressing but no specific bleeding point could be found. Patient's course continued downhill the

pulse became more rapid and thready, and she died on eleventh day after operation. Final diagnosis was ruptured appendix with pylephlebitis, generalized peritonitis.

CASE 5 J M, admitted to Newark City Hospital January 4, 1931, 39 year old colored longshoreman, complained of severe abdominal pain around umbilicus which had been present for past week. No nausea or vomiting occurred. Several hours before admission patient had a chill. He has had a high fever during past week. Examination showed an undernourished colored male complaining of severe pain in the abdomen and having definite chill at time of examination. Temperature was 101.4 degrees, pulse, 96, respirations, 34. The abdomen was markedly rigid especially on the right side, with rebound tenderness. A diagnosis was made of ruptured appendix. Operation was performed 1 hour after admission through a lower right rectus incision. Fluid and free pus were noted in the abdominal cavity. A rubber drain was inserted. The appendix was not removed. Patient's temperature continued high. The pulse was weak, rapid, and irregular. Fluids were given freely intravenously. A post-operative chill occurred on third and fourth days. Patient succumbed on fifth day from acute suppurative appendicitis with localized abscess and pylephlebitis of appendicial vein. No autopsy was obtained.

CASE 6 E G, admitted to the Newark City Hospital October 2, 1935, white male, 26 years old; gave a history of pain in the right lower quadrant since previous afternoon. He had vomited that night and several times the morning of admission. He has been nauseated continuously. There was a history of a similar previous attack in April. Patient had a chill the previous evening and another chill immediately after admission. Temperature on admission was 104.8 degrees, pulse, 124, and respirations, 26. Examination showed direct and rebound tenderness all over the lower abdomen, with some rigidity. No masses were palpable. White blood count before operation was 21,250 with 94 per cent polymorphonuclears. A diagnosis was made of acute gangrenous appendicitis with thrombophlebitis. He was operated upon 8 hours after admission by Dr. C. MacArthur. Operative note reads: "Low right rectus incision, rectus muscle pushed aside medially and peritoneum was opened at its lateral border. Appendix was found gangrenous, firmly adherent, firmly surrounded by fresh adhesions. The ileocolic vein and its tributaries were opened and examined for the presence of thrombi. All appeared normal. The ileocolic vein was ligated about 4 inches above the ileocecal valve. Appendix was then freed with difficulty and removed. Stump inverted. Abdomen closed in layers. Two silver drains under fascia." Fluids were given intravenously after operation. Within 24 hours the temperature fell to 100.0 degrees. He made an uneventful recovery except for symptoms of acute bronchitis, a few fine râles being found at both bases.

Patient was discharged on the twenty-first day after operation.

CASE 7 J T, white male, age 42 years, was admitted to St. James Hospital on October 13, 1936, with a history of having had a dull ache in the right side of the abdomen for the past week. The day before admission the pain became severe, he vomited once. He took a cathartic and an enema, and treated himself with moderate amounts of whisky for the pain. The night before admission he had a chill lasting several minutes. On examination there was found slight rigidity in the right lower quadrant. A soft mass was noted in the right side which was acutely tender, with rebound tenderness. Temperature was 101.4 degrees; pulse, 98, respirations, 24. He was operated upon 1 hour after admission, through a McBurney incision. A gangrenous appendix was found wrapped up in omentum. The appendix was removed, the stump was inverted, and the mesoappendix was ligated high. One Penrose drain was placed in the pelvis through a stab wound. The patient had no further chills. He had a stormy course for 12 days with temperature ranging up to 103.0 degrees. The temperature was probably due to an acute bronchitis with patchy pneumonia. After the twelfth day his temperature remained normal. He was discharged on the twenty-first day after operation.

CASE 8. H D, admitted to Newark City Hospital May 10, 1936, white female, 40 years old, with a history of pain in the right lower quadrant for 2 days before admission. She vomited several times after taking a laxative. The day previous to admission she had several shaking chills with fever. She continued to vomit. The abdominal pain became more generalized. She had eaten very little since becoming sick. On admission the temperature was 102.0 degrees, pulse, 110, respirations, 28. Examination of the abdomen revealed marked generalized rigidity and tenderness which was more marked in the right lower quadrant. The urine was negative. A diagnosis was made of a ruptured appendix with thrombophlebitis of the appendicial vein. Operation was performed under spinal anesthesia through a right rectus incision 3 hours after admission. When the peritoneum was opened free purulent fluid welled up. The intestines were packed away with rubber covered sponges, and the ileocolic vein was ligated above its bifurcation about 4 inches away from the ileocecal junction. It was easily identified, and bled freely at the point of ligation. No thrombus was seen. The appendix was then sought and was found to be ruptured and separated from the cecum at its base, lying free in the peritoneal cavity. It was removed after ligation of the mesentery. The stump could not be inverted, but was tied. Three Penrose drains were inserted through a stab wound, one in the pelvis and two in the right gutter. The abdomen was closed in layers with silver drains under the fascia. Duodenal suction drainage was started as soon as patient reacted. She was given large amounts of fluids intravenously daily. She

was desperately ill from the onset, she was irrational and semicomatose a good part of the time. Abdominal distention could not be controlled by any measures. Her temperature never fell below its preoperative level and spiked well above that level each day. She died 7 days after operation with a generalized peritonitis. No autopsy was obtained. She had no chills after operation.

STUDY OF CASES

Although the number of cases in this series is small, it is the largest to be presented thus far in which the same principles of treatment have been applied, and may be summarized as follows:

Age, sex, race. A recent study of 1463 consecutive cases of appendicitis made at the Newark City Hospital (27) may be used for statistical comparison. In this large series of cases covering all types of appendicitis, 81 per cent of the total occurred between the ages of 10 and 40. The average age in the present series is within approximately the same range. The ratio of colored to white is also found to be the same, approximately 1 to 11. In the large series the sex ratio of male to female was found to be approximately equal, whereas in this group the ratio was 3 to 1 in favor of males. It will thus be seen that, unlike the ratio existing in all types of appendicitis, the condition under discussion is more frequent in men than in women. Boyd states that acute fulminating appendicitis is twice as common in the male as in the female. When the sex incidence of acute cases in the large series is studied alone, the disease is found to be twice as common in men as in women (27) concurring with Boyd. Even then, the ratio is not as high as the 3 to 1 ratio found in the 24 acute cases outlined in this paper.

Symptoms. The symptoms in these cases were those of acute appendicitis with abdominal pain which was either generalized or localized in the right lower quadrant and was associated with nausea and vomiting. The length of time between the beginning of symptoms and the time of admission to the hospital was longer in this group of cases, probably because of the chill which confused the usual clinical picture of acute appendicitis and prevented earlier admission of the

patient to the hospital and thus delayed operation. The average duration of symptoms in the patients who died was 5.5 days before operative interference. Four of these patients presented symptoms for 1 week or longer. There is thus a definite relationship between the duration of symptoms and mortality. None of the patients presented obvious complications before operation with the exception of 2, in one of whom pregnancy was advanced (18), the other jaundiced.

Diagnosis. On reaching the surgical service of the hospital, the diagnosis of acute appendicitis with pylephlebitis was made in 18 cases and immediate operations were performed. Of the 6 remaining, the diagnosis of acute appendicitis was made in 4, while immediate operation for acute pancreatitis was proposed in 1 of the others. The sixth case was that of a patient who was in the medical service for 5 days under a different diagnosis until a surgical consultation was called. These facts are cited in order to show that if the clinical entity now in question is kept in mind, that is to say, the signs of acute appendicitis with a chill, the correct diagnosis is not difficult. It is only when the chill is interpreted erroneously that delay occurs or the wrong diagnosis is made.

Complications. The main complications found in this series were peritonitis local or general and liver abscess. Of those that developed a liver abscess, 6 in number all died. In 4 patients an upper respiratory infection developed, and one patient died although the respiratory condition was not the immediate cause of death. Case 14 of the proved group deserves special recognition in that there was no preoperative chill and in that the appendix was removed without the presence of thrombosed veins being noted. The appendix however, was gangrenous. This man was without symptoms of pylephlebitis for 17 days after operation and was apparently well on the way to recovery, when one of the Penrose drains was moved. Following the moving of the drain he suffered a chill and when another Penrose drain was moved 6 days later again there were chills. The termination was fatal, and liver abscesses were found at necropsy. It is thought that the drains must have been

contiguous to small thrombosed venous radi-
cles and that the trauma caused by moving
them dislodged small emboli from within these
veins

Hospitalization In those patients who re-
covered, the stay in the hospital was found
to be that of the average case of uncomplicated
fulminating appendicitis. In most of the fatal
cases the patients remained alive for many days
after operation. This is not unusual in cases of
this nature. They live for many days after
operation has been performed, but once the
pathology is established they resist all at-
tempts at cure.

Blood cultures. Although there were 8
deaths in the series here reported, and al-
though in most instances necropsy revealed
multiple abscesses of the liver, it is to be noted
that, although blood cultures were taken in all
of them, a positive result was obtained in
only one (Case 14), and then late in the dis-
ease. The liver apparently acts as a sieve,
straining the emboli into its capillary bed.
The infected emboli then produce abscesses,
but there is no contamination of the general
stream until one or more of the abscesses
breaks into the circulation. This fact is im-
portant since undue weight may be attached
to negative blood cultures. In the light of this
experience, it has been decided that, in future,
a culture of blood from the interrupted ileo-
colic vein will be taken at the time of opera-
tion for study in comparison with systemic
blood taken at the same time.

Type of appendicitis. The operative records
in 22 of the 24 cases state that the appendix
was gangrenous. In 8 of the 22 cases it was
also ruptured. In the 2 remaining appendices,
in 1 a diagnosis of suppurative appendicitis
was made and the other was described as
"thick and acutely inflamed."

Mortality There were 8 deaths in the group
of cases here collected, a mortality of 33 per
cent. This figure is above the average rate
reported from many large clinics dealing with
ruptured or gangrenous appendices. There is
undoubtedly a relationship between the dura-
tion of symptoms and death, and it is probable
that the mortality rate can be lowered if the
disease is recognized by the physician who first
sees the patient.

There are at least two ways in which the
factor of delay affects the outcome unfavor-
ably. First, the probability of embolism in-
creases with time. Second, advanced peri-
tonitis makes identification of the site of the
thrombus and ligation of the affected vein
difficult, if not impossible. Thus, in the 16
proved cases, 5 of the patients died. In 4 of
these (Cases 2, 10, 12, 14), the diagnosis was
not made until from 4 days to 3 weeks after
the onset of symptoms; in the fifth case
(Case 9) no satisfactory ligation could be done
because of peritonitis. Of the 11 cases in
which the patients survived, 1 case (Case 1)
was delayed and 10 were recognized early but
ligation was satisfactorily performed in all.

SUMMARY AND CONCLUSIONS

1. The occurrence of a chill and typical
symptoms of acute appendicitis point to a
complicating thrombophlebitis of the appendi-
cinal vein.

2. A study is presented of appendicitis
complicated by thrombophlebitis of the ap-
pendicinal vein, with a report of 16 proved and
8 presumptive cases.

3. The treatment consists in ligation of the
ileocolic vein above the thrombus before ap-
pendectomy is performed.

4. Unless the condition is treated early and
the ileocolic vein ligated, emboli may occur,
causing either pyelphlebitis or liver abscesses.

5. It is believed that early recognition and
proper treatment of this type of appendicitis
may contribute to lowering the mortality rate
of appendicitis as a whole.

I should like to express my appreciation to Dr. E. Zeh
Hawkes and Dr. Royal A. Schaaf for their stimulation and
counsel in preparing this paper, and for permission to re-
port some of these cases.

was desperately ill from the onset she was irrational and semicomatose a good part of the time. Abdominal distention could not be controlled by any measures. Her temperature never fell below its pre-operative level and spiked well above that level each day. She died 7 days after operation with a generalized peritonitis. No autopsy was obtained. She had no chills after operation.

STUDY OF CASES

Although the number of cases in this series is small, it is the largest to be presented thus far in which the same principles of treatment have been applied, and may be summarized as follows:

Age, sex, race. A recent study of 1463 consecutive cases of appendicitis made at the Newark City Hospital (27) may be used for statistical comparison. In this large series of cases covering all types of appendicitis, 81 per cent of the total occurred between the ages of 10 and 40. The average age in the present series is within approximately the same range. The ratio of colored to white is also found to be the same, approximately 1 to 11. In the large series the sex ratio of male to female was found to be approximately equal, whereas in this group the ratio was 3 to 1 in favor of males. It will thus be seen that, unlike the ratio existing in all types of appendicitis, the condition under discussion is more frequent in men than in women. Boyd states that acute fulminating appendicitis is twice as common in the male as in the female. When the sex incidence of acute cases in the large series is studied alone, the disease is found to be twice as common in men as in women (27), concurring with Boyd. Even then, the ratio is not as high as the 3 to 1 ratio found in the 24 acute cases outlined in this paper.

Symptoms. The symptoms in these cases were those of acute appendicitis with abdominal pain which was either generalized or localized in the right lower quadrant and was associated with nausea and vomiting. The length of time between the beginning of symptoms and the time of admission to the hospital was longer in this group of cases probably because of the chill which confused the usual clinical picture of acute appendicitis and prevented earlier admission of the

patient to the hospital and thus delayed operation. The average duration of symptoms in the patients who died was 5.5 days before operative interference. Four of these patients presented symptoms for 1 week or longer. There is thus a definite relationship between the duration of symptoms and mortality. None of the patients presented obvious complications before operation with the exception of 2, in one of whom pregnancy was advanced (18), the other jaundiced.

Diagnosis. On reaching the surgical service of the hospital, the diagnosis of acute appendicitis with pylephlebitis was made in 18 cases and immediate operations were performed. Of the 6 remaining, the diagnosis of acute appendicitis was made in 4 while immediate operation for acute pancreatitis was proposed in 1 of the others. The sixth case was that of a patient who was in the medical service for 5 days under a different diagnosis until a surgical consultation was called. These facts are cited in order to show that, if the clinical entity now in question is kept in mind, that is to say, the signs of acute appendicitis with a chill, the correct diagnosis is not difficult. It is only when the chill is interpreted erroneously that delay occurs or the wrong diagnosis is made.

Complications. The main complications found in this series were peritonitis, local or general, and liver abscess. Of those that developed a liver abscess, 6 in number, all died. In 4 patients an upper respiratory infection developed, and one patient died although the respiratory condition was not the immediate cause of death. Case 14 of the proved group deserves special recognition in that there was no pre-operative chill and in that the appendix was removed without the presence of thrombosed veins being noted. The appendix however, was gangrenous. This man was without symptoms of pylephlebitis for 17 days after operation and was apparently well on the way to recovery when one of the Penrose drains was moved. Following the moving of the drain he suffered a chill and when another Penrose drain was moved 6 days later again there were chills. The termination was fatal and liver abscesses were found at necropsy. It is thought that the drains must have been

THE CONSERVATIVE TREATMENT OF GALL-BLADDER DISEASE

HARRY E. MOCK, M.D., F.A.C.S., CLARENCE F. G. BROWN, M.D., and
RALPH E. DOLKART, M.S., Chicago, Illinois

A CRITICAL survey of the medical and surgical management of gall-bladder disease leads to the inevitable conclusion that present day therapy is inadequate. From the surgeon's point of view, the consensus is that if there is any evidence of pathological changes in the gall bladder, the structure should be immediately removed. From the internist's point of view, the use of the low fat, low cholesterol diet in conjunction with catharsis comprises the average conception of the medical management of gall-bladder disease and has remained unchanged as the treatment of choice for the past three or four decades.

We do not concur with either of these generally accepted ideas of gall-bladder management. Cholecystectomy, which for two decades has been the most popular form of surgical treatment, is not always indicated when surgery is performed, neither has it relieved the symptoms in a reasonable proportion of the cases in which it is used. Cholecystostomy has a more definite place in gall-bladder surgery than recent surgical trends would indicate. The fact that roentgenologically functioning gall bladders can be demonstrated after surgical drainage has apparently been totally disregarded. A great majority of patients with low grade right upper quadrant symptoms can be as completely or more completely relieved by proper medical management than by surgery. The inadequacy of the present popular medical management of gall-bladder disease accounts for the dominance of surgical treatment. Medical management, however, based upon the physiological principles of the biliary tract will relieve symptoms and can restore to normal roentgenological functioning, gall bladders which gave

pathological findings on previous examination.

The objective of the present study is to correlate conservative surgical ideas with medical opinion guided by recent advances in the knowledge of the physiology of the biliary tract. In our opinion the management of biliary tract disease can never be designated as solely surgical or entirely medical. We believe that there is much to be gained in the knowledge of the disease by the co-operation of clinicians who of necessity see the patients from different points of view.

As one of the chief factors concerned in the production of upper abdominal distress, the pathological gall bladder is of great significance. In a series of 850 patients seen in the gastro-intestinal clinic of the St. Luke's Hospital Out-Patient Department over a 5 year period, the gall bladder was found to be the causative agent in the majority of cases. The results obtained in this clinic on the incidence of pathological changes in the gall bladder in cases of distress referable to the gastro-intestinal tract compare favorably with statistical studies by Davis and Vander Hoof, Bladeford and Droger, and Foster, on over 7,000 patients. Table I shows the results of our findings.

TABLE I—DIAGNOSES IN PATIENTS COMPLAINING OF UPPER ABDOMINAL DISTRESS—850 CASES

Diagnosis ¹	Cases	Per cent
Gall-bladder disease	239	28.1
Functional nervousness	183	21.6
Gastroduodenal ulceration	165	19.5
Systemic causes	52	6.2
Neoplasms	37	4.3
Miscellaneous—reflex intestinal, appendix, amebiasis, ulcerative colitis, etc.	171	20.0

flow. Magnesium sulphate has been employed as a cholagogue for many years because of its action in relaxing the sphincter of Oddi. It is difficult, however, to correlate the rationale of the popular low fat low cholesterol dietary and magnesium sulphate therapy. If stasis is to be overcome, then the most physiological method of inducing evacuation of the gall bladder—the presence of fat in the duodenum—is totally disregarded. A low fat diet places the gall bladder at rest, whereas magnesium sulphate achieves a directly antagonistic action. We fail to see the logic in abandoning a physiological method of inducing gall-bladder emptying and substituting an artificial mechanism. Furthermore, according to Ivy (27), the consensus is that magnesium sulphate is not as effective as egg yolk and cream or as olive oil and oleic acid.

Although a large percentage of patients with diseased gall bladders are chronically constipated and magnesium sulphate does have a cathartic action, the end-result of its continued use is generally the development of a highly irritable bowel with accompanying reflex pylorospasm to add to the original complaints referable to the gall bladder. When this latter syndrome is produced in a patient with hyperactive visceral reflexes, the production of a gall-bladder dyskinesia often follows.

The second inconsistency in this form of gall-bladder management is the limitation of foods high in cholesterol. We have been unable to find any conclusive evidence that there is any hypercholesteremia in patients with cholelithiasis. Whitaker, quoting Fowweather and Collinson, states that hypercholesteremia is the most significant aberration of the blood in cholelithiasis, a relation between the two conditions having been often observed in patients. Andrews (15) in a series of 250 patients with gall stones made studies of the blood levels of cholesterol and found no correlation. Campbell has likewise shown that the average patient with gall stones has a normal level of blood cholesterol. In recent months we have run blood cholesterol determinations routinely on patients under our observation for gall-bladder disease. Elevations of the blood cholesterol have been found

only in those patients who have a clinically demonstrable hypothyroidism or who have or just have had obstructive jaundice.

Whitaker has also attached undue significance to the experimental feeding of diets high in cholesterol to laboratory animals. Quoting Hansen and Dewey, he states that overfeeding with lipids, or intraperitoneal injections of cholesterol emulsions, can produce an increase of cholesterol in the blood as well as masses resembling gall stones in the bile. Studies by Fox, Gardner and Gainsborough, McMaster and Elman, Andrews and Dostal (1), Jones, and others do not support these findings, and on the contrary definitely indicate that cholesterol in the diet has no relation to either the blood or bile levels. Further studies by Andrews in humans show that there is no correlation.

The factors of primary infection and re-infection in producing the pathological gall-bladder have long formed the basis of treatment in many proposed forms of management. Salicylates, hexamines, and other substances have been employed, as gall-bladder "disinfectants." Besides the irritating effect of these substances, especially the salicylates, upon the stomach outlet, it does not appear that infection plays an especially significant part. From their investigations of gall bladders removed at operation, Andrews and Henry (2) conclude that infection is only a secondary factor, mechanical factors being primary. Similar observations with conclusions that cultures of bile or tissue from different portions of the biliary tract are sterile in a considerable proportion of cases have been reported by Rehfuess and Nelson (40), Hanssen and Yurevich, and others. In this connection, one of us (H. E. M.) has cultured all bile drained from gall bladders at operation and in 50 consecutive cases was unable to obtain growth of pathogenic organisms.

In addition to the problems of stasis and infection, the third problem with which adequate medical management must cope is the liver damage associated with the pathological changes in the gall bladder. In 1918 Graham (22) reported varying degrees of hepatitis constantly present with cholecystitis. Numerous subsequent workers have reported

TABLE II—RESULTS OF BILIARY TRACT SURGERY—1823 CASES

Reported by	Year	Cases	Diagnosis	Results	
				Satisfactory	Unsatisfactory
Davis (11)	1928	144	Mixed	90.0%	9.0%
Coffey (10)	1910	524	Mixed	69.8%	30.2%
Stanton (13)	1912	90	Stoneless	51.0%	49.0%
Judd and Priestley (15)	1932	72	Stoneless	82.5%	17.5%
Judd and Priestley (15)	1932	534	With stones	76.2%	23.8%
Gillich and Gullone (1)	1931	96	Mixed	63.8%	36.2%
Howard (26) and Brown (3)	1914	63	Mixed	44.5%	55.5%

Mixed—designates both stone and non stone cases

A study of various published statistics concerning the surgical treatment of gall bladder disease suggests that surgery alone has proved inadequate in a considerable portion of the cases. A more prolonged period of observation with a more careful selection of the cases requiring surgery combined with a better understanding of the proper medical management of biliary tract disease would greatly reduce the number of surgical failures. In many instances intelligent postoperative medical management is necessary to complete the cure. Failure to develop a satisfactory medical management of many gall bladder conditions has thrown all these cases into the realm of surgery.

It is difficult, however, to evaluate the results of surgery as reported in the literature upon an equitable basis due to the different criteria of improvement used by the various authors. Some of the investigators have arbitrarily differentiated between complete and relative cures and improvement. In compiling Table II, results were considered only as satisfactory or unsatisfactory. Cases designated in the literature as improved only and not even relatively cured have been classed as unsatisfactory in this tabulation.

It is significant that the more conservative the criteria of improvement and the longer the duration of the postoperative periods of observation, the less effective were the results of surgery. In Stanton's series of 90 stoneless cases followed for an average of 3.5 years after operation, no relief was obtained by 47.0 per

cent of the patients. Following patients post-operatively over long periods of time and using similar rigid standards of cure, Howard and Brown found that 20.6 per cent of the 55.6 per cent of the patients designated as unsatisfactory in the table obtained no relief whatsoever from surgery in their cases.

The available data indicate quite definitely that approximately one third of all patients subjected to biliary tract surgery show little or no improvement after operation. Two distinct conclusions become evident: first, there is a definite need for a more careful selection of cases for operation; second, adequate medical management is a problem of paramount importance. Apparently the best subjective results are obtained in patients subjected to surgery who give histories of repeated colic, common duct stone, or chronic pancreatitis. Poorest results obtained in patients in whom cholecystitis existed without cholelithiasis.

We believe that there are several fundamental conditions which require consideration in the medical and surgical management of a diseased gall bladder. These are: (1) stasis in the biliary tract; (2) infection of the gall bladder; (3) the varying degrees of hepatitis and liver damage accompanying the changes in the gall bladder; (4) pericholecystitis with adhesions to adjacent viscera; (5) accompanying pancreatitis. The result of stasis or blocking at the sphincter of Oddi. The exact rôle of each factor in the production of the characteristic syndrome of gall bladder disease is not definite and varies in the individual patient.

As early as 1892 Naunyn postulated his well known stasis infection conception of the etiology of gall stones. Since that time numerous workers have emphasized bile stasis as one of the critical phenomena associated with the pathological gall bladder. Elimination of bile stasis or palliation thereof was the basis for Lyon's duodenal drainage therapy. Many modifications of his original technique (34, 35) have been suggested. Although some few clinicians still employ duodenal drainage the results in general are too inconstant to warrant widespread usage.

A great many chologogic preparations have been used in the past in order to stimulate bile

minimizing the place of surgical treatment. The point which we wish to emphasize is that there should be a definite revision of ideas as to just what constitutes adequate medical management and what are surgical indications.

Before discussing the surgical aspects of the problem there are certain general considerations which must be kept in mind. In the first place, the clinician attempting medical management must know that procrastination in the face of well defined surgical indications is not without hazard. As Ivy (28) has pointed out, the older a patient becomes, the higher the mortality in biliary tract operations. The second point to be kept in mind is that in the presence of multiple small stones, the sudden impaction of a calculus in the common duct is an omnipresent danger. Rehfuess and Nelson (41), in an analysis of a large number of cases, found that approximately 30 per cent of all patients with cholelithiasis present symptoms of obstruction at some time. Further studies by Judd and Marshall (31), however, indicate that complete obstruction occurs in a relatively small proportion of cases of common duct stones. In their series of 1,608 patients with common duct stone, 27 per cent had not been icteric.

Some authors have stressed the fact that primary carcinoma of the gall bladder or biliary tract has a higher incidence in patients with cholelithiasis. Vincent has recently stated that at least 70 per cent of the cases of malignant disease of the gall bladder and common duct occur in association with stones. In a series of 9,550 gall bladders removed surgically at the Mayo Clinic, Wellbrock reports the finding of 69 adenomas. Of this number, however, only 38 were associated with stones and only 2 were malignant, 1 of the latter occurring in a non-calculous gall bladder.

In the absence of other indications, there are 3 groups of gall-bladder disease which we believe will respond to physiological medical management: (1) The gall-bladder dyskinesias, (2) chronic cholecystitis where no calculi are present; (3) chronic cholecystitis with large soft calculi, few in number, and with which the patients have no, or very infre-

quent, colic-like attacks. Even in this latter group we have found that a large number of patients become relatively symptom free when treated by the methods we have described (6, 7). Such patients, however, who do not respond to a reasonable trial period of such therapy should receive surgical treatment without further delay.

As with most surgical conditions, the clinician is usually confronted with a perplexing problem when the patient either flatly refuses operation or is such a poor surgical risk that medical management is required. Such patients are not few, and we have found that the program of management as herein outlined is the most satisfactory form of palliative treatment.

WHAT ARE THE INDICATIONS FOR OPERATION IN GALL-BLADDER DISEASE?

Enumerated in their order of frequency with our opinion concerning *when* to operate, the following are definite indications:

1. *Cholelithiasis giving definite gall-stone colic.* As a rule it is advisable to permit the attack to subside or abate before operating. There are cases, however, in which the severe pain persists, the icterus increases, and the patient's condition is growing worse. In this type of acute gall bladder, early operation is preferable.

2. *Empyema of the gall bladder.* In the acute cases in which the patient has chills and fever and is definitely growing worse, immediate operation is indicated.

3. *Obstructed cystic duct with a markedly dilated gall bladder.* Such a gall bladder is often filled with white bile. Infection may develop. At times it becomes difficult to distinguish between empyema and white bile. In some cases the gall bladder may be so stained and distended with thick dark bile that it resembles a gangrenous gall bladder. In other instances the gall bladder may rupture. The condition is definitely surgical and should be operated upon when diagnosed.

4. *Obstructive jaundice.* This condition is due as a rule to a common duct stone, stricture of the common duct, or to extrabiliary tract inflammation with compression of the duct, either from a subacute or chronic pancrea-

similar findings Flint in 1930 reported a series of 34 cases in which both gross and microscopic studies from biopsy specimens removed at operation demonstrated hepatitis associated with cholecystitis in the majority of cases. Levulose tolerance tests run on the same patients closely agreed with the microscopic evidence of liver damage. T. R. Brown (8) has stated that there is good evidence that certain of chronic gall bladder cases in reality present symptoms far more referable to a diseased liver and biliary tract than to the gall bladder alone.

Many consider the existence of a hepatitis to be a definite surgical indication regardless of the severity of the gall bladder complaints. They point out the fact that were the gall bladder not removed, the hepatitis would be aggravated. Even if hepatitis has not become evident by means of laboratory and clinical studies they state that the gall bladder should be removed before liver damage does occur. Such concepts are well founded if stasis cannot be alleviated by medical management and bile is permitted to stagnate in the biliary tree. Stasis frequently affects the pancreas as well as the liver leading to subacute or chronic pancreatitis. This condition yields best to a prolonged drainage and, when present, contra indicates removal of the gall bladder, in the opinion of many authorities. It should be remembered however, that the liver and pancreas have remarkable regenerative powers, and if stagnation of bile can be prevented medically, one of the important indications for surgical intervention can be eliminated. Furthermore, it is well established that removal of the gall bladder is followed by compensatory dilatation of the entire biliary duct system due to disturbances of the pressure regulatory mechanism of the biliary tract. It is questionable whether such a reaction favors alleviation of an existent hepatitis. In this connection, Kohlstaedt and Helmer studied the hippuric acid excretion as a test of liver function, employing the method described by Quick in 1933, in a series of 22 cases of extrahepatic biliary tract disease which were subjected to surgery. The results of the test varied widely. In 3 cases tests were made after the patients had completely re-

covered from the surgical procedure. The hepatic function, which had been lowered pre-operatively, did not return to normal in any of these cases.

In a previous paper (6) we reported the results of treatment of 65 cases of chronic cholecystitis, both with and without calculi, by various methods of medical management. Patients under observation were followed at 30 day intervals with cholecystographic examination. Our findings definitely indicated that patients can be managed medically, so as to become relatively symptom free and ultimately have a roentgenologically normal gall bladder in many cases. While gall bladders with calculi did not show the roentgen improvement that the stoneless gall bladders did, the subjective improvement was consistent. Best results both subjectively and objectively from roentgenologic studies were obtained by simultaneously administering (1) ketocholanic acids¹ to stimulate the flow of hepatic bile, (2) hourly feedings of milk and cream to induce contraction and emptying of the gall bladder at frequent intervals, (3) antispasmodic medication (tincture of belladonna m. viii, elixir of phenobarbital grs $\frac{1}{2}$, t. i. d.) to diminish the irritability of the gastrointestinal tract, thereby alleviating stasis due to hypertonicity. In severe cases bed rest was necessary at the time this form of management was started.

In a subsequent study (7) the results of the treatment of an additional group of 55 cases of chronic gall bladder disease showed that a large percentage of patients were able to obtain relief upon this form of medical management.

The choice of ketocholanic acids for the purpose of stimulating the secretion of bile was based upon experimental studies upon laboratory animals (37). Our studies, carried out in collaboration with Dr. K. K. Jones indicated that greater cholerisis with less toxic manifestations could be obtained using this preparation of bile acids.

Although our observations clearly demonstrate the efficacy of medical management based upon sound physiological principles there should be no misconception that we are

¹Ketocholanic acid supplied by the G. D. Searle and Company, Chicago.

performed were studied roentgenologically from 1 to 10 years after operation. Six of the 10 patients showed a normal response to the Graham-Cole test and 8 of them were free from symptoms.

It was further observed by several of the internists on the St. Luke's staff that poor results were being obtained in the patients subjected to routine cholecystectomy. Further studies were therefore carried on by Jenkinson and Foley in the roentgenologic department. Twenty-eight patients who had been treated by cholecystostomy from 8 months to 20 years previously were subjected to a complete series of cholecystographic examinations. Seven of the patients were males ranging in age from 43 to 78 years. Twenty-one were females between the ages of 32 and 66 years. At the time of operation the gall bladders were drained from 8 days to 4 weeks. *Nineteen of these patients gave a dye response that demonstrated a gall bladder which filled and emptied normally and gave a homogeneous shadow. Two gave normally functioning gall bladders with slight defects in contour. Seven were definitely pathological.* Twenty-one or approximately 70 per cent of these patients previously subjected to surgical drainage gave a normal response.

Additional studies (H. E. M.) on private patients previously cholecystostomized showed that 68 per cent of a total of 40 patients gave a normal gall-bladder visualization. These two groups of cases show that gall bladders which have been subjected to surgical drainage can be objectively demonstrated to be capable of carrying on normal function. We definitely believe, therefore, that it is not unorthodox to endeavor to preserve the normal physiological activity of the gall bladder and biliary tract whenever possible.

In our opinion cholecystostomy is indicated:

1. Whenever, after exposing the gall bladder and carefully examining the liver and the pancreas, one finds a definite condition of subacute or chronic pancreatitis is present, with or without cholecystitis or stones, provided the gall bladder is not so diseased that it must be removed.

It is the experience of one of us (H. E. M.)

and confirmed by the writings of Archibald, de Tarnowsky, and others, that when the gall bladder is drained because of an existing chronic pancreatitis, prolonged drainage for 6 to 12 weeks is preferable to the usual few days to 2 weeks. The recurrences and the cases that continue to have upper right quadrant distress most frequently follow a short drainage period. Bile drainage gives the inflammatory changes in the pancreas the best chance for resolution, a condition which usually requires weeks and months.

2. Whenever a few stones, usually cholesterol, are found in a gall bladder which on close inspection is otherwise negative. Because it has become the container of stones is not a sufficient reason for removing the gall bladder. We are convinced that the percentage of cures in this group is just as high, if not higher, than when the gall bladder is removed. Furthermore the operation is simpler.

3. In the presence of acute empyema of the gall bladder, it is our opinion that a quick drainage operation is safer and preferable to the more prolonged cholecystectomy.

When the surgeon exposes the gall bladder and biliary tract expecting to find stones and fails to find any condition indicative of pathological changes, it is far wiser to back out than to remove or even drain such a gall bladder. The day is past when this organ should be considered a useless non-functioning vestigial structure.

Cholecystectomy is definitely indicated when a diseased, distended, stone laden gall bladder is found. In the more severe forms of biliary tract disease, it still is and probably always will be more frequently indicated than is cholecystostomy. It is not our purpose to condemn or belittle this procedure. Rather ours is a plea for a more careful individualization of every case instead of subjecting each patient with gall-bladder disease to a routine cholecystectomy.

CONCLUSIONS

1. We believe that the present conceptions of the medical management of gall-bladder disease using low fat, low cholesterol diets in conjunction with saline purgatives have no sound physiological basis.

titis or from an extrabiliary or intrabiliary tumor. Such patients should be observed carefully and be subjected to operation when the obstructive jaundice is lessening or has subsided. Even these patients, however, occasionally have to be operated upon during the acute jaundiced stage to save the patient's life.

5 *Subacute or chronic pancreatitis, usually accompanying a cholecystitis.* As a general rule such patients should be placed upon careful medical management. Operation is indicated if the symptoms fail to subside after a few weeks or if the condition is definitely growing worse. In 3 cases which one of us (H. E. M.) had, the attacks were very acute, the jaundice very marked, and the patients grew progressively worse. All 3 patients were operated upon from the second to the seventh day. In each case the gall bladder was distended and the pancreas definitely enlarged. In 1 case the swollen pancreas simulated a tumor the size of a baseball. Prolonged drainage of the gall bladder was the operative procedure in all cases. All 3 recovered.

6 *Cholecystitis.* In most instances when this diagnosis is made the patient is definitely a medical rather than a surgical problem. The majority will readily improve on careful medical management. When no improvement occurs after persistent effort surgery is justified. Usually a careful investigation of the pancreas at the time of operation will reveal changes typical of chronic pancreatitis.

7 *Gangrenous gall bladder.* This is presumably a rare condition but according to Bailey, of St. Louis, is more common than the profession realizes. It usually results from recurring attacks of cholelithiasis colic with accompanying gall bladder inflammation and fibrosis and this combined with gall stone pressure at the neck of the bladder so interferes with the circulation that an area of necrosis develops. The gangrene may be of only a small portion of the wall or may extend to include most of the organ. Rupture is not infrequent. The mortality rate is very high, especially in the older patients. It is seldom diagnosed except at operation. The threat of this condition developing is a strong argument in favor of surgery in the presence of

recurring attacks of gall bladder disease, unrelieved by medical management.

The indefinite upper right quadrant syndrome that may mean dysfunction of the biliary tract, pancreas, duodenum, or stomach rarely belongs in the field of surgery. In all of these cases the gall bladder may at times fail to visualize normally. Patients presenting these indefinite complaints should not be subjected to operation without prolonged careful medical management. It should be remembered likewise that there are probably more patients still enjoying comfortable existence with adhesions about the gall bladder or malformations of this organ than have ever been operated upon for such conditions. The majority of such patients are suffering from functional conditions only temporarily relieved by surgery. It is the surgical treatment of such patients that accounts for the high percentage of unsatisfactory surgical results.

WHEN SURGERY IS PERFORMED WHAT IS THE OPERATIVE PROCEDURE RELATIVE TO THE REMOVAL OR DRAINAGE OF THE GALL BLADDER?

It is almost unorthodox for a surgeon to express even a favorable opinion concerning cholecystostomy. In our opinion however, there are very definite physiological indications for this procedure. We concur with Ivy's view that the gall bladder that concentrates should not be removed except for very definite indications.

It has been stated by several authors in the past that the drained gall bladder never gives a normal response upon roentgenologic examination. This has been one of the strong arguments in favor of the total removal of all gall bladders. It has swung the majority of surgeons to the "ectomy," as against the "ostomy" side of gall bladder surgery. In 1927 Spurling and Whitaker examined the gall bladders of 12 patients by the Graham-Cole test after they had been subjected to surgical drainage. They found that none of the gall bladders visualized. Moore (23) in 1928 confirmed the findings of these authors. One of us (H. L. M.) was unable to substantiate these findings. Ten patients upon whom cholecystostomies had previously been

2 On the basis of our studies of 120 patients with chronic gall bladder disease, we have found that the use of hourly feedings of milk and cream to induce contraction and emptying of the gall bladder, ketocholanic acids to stimulate the flow of hepatic bile, and antispasmodic medication to diminish the irritability of the gastro intestinal tract, effectively relieve symptoms and reduce the incidence of colic in the majority of cases

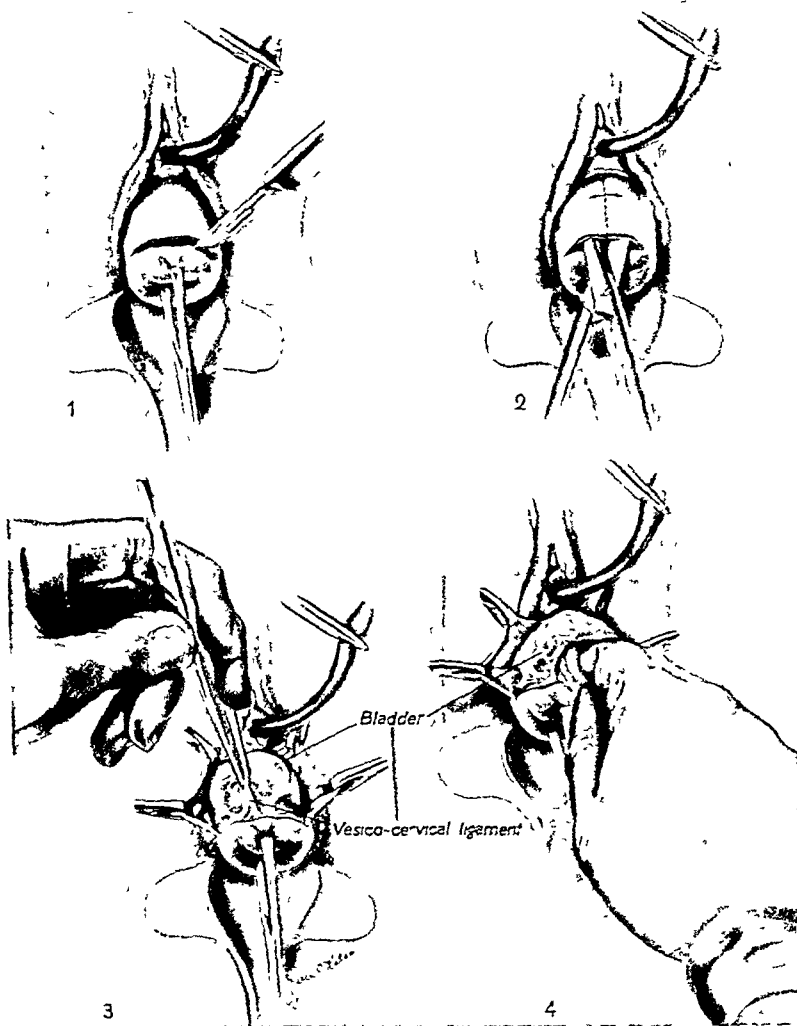

3 Statistical data indicate the persistence of morbidity in patients with gall bladder disease following approximately one third of all operations upon the biliary tract In a large number of patients, therefore, an adequate program of medical management would be preferable to surgery

4 Removal of the gall bladder does not necessarily bring relief to patients with chronic gall bladder disease, especially if associated with pancreatitis, unless colic and intermittent obstruction has been the predominant clinical picture In our opinion routine cholecystectomy is an unwarranted procedure and in many cases surgical drainage would be preferable

5 There should be a definite revision of ideas as to what constitutes adequate medical management and what constitutes indications for surgery in patients with chronic gall-bladder disease

Figs 1 to 16 show the various steps in the operative procedure

about 1 centimeter above the anterior cervical lip. This incision is carried through the mucous membrane and the closely underlying and adherent fascia down to hard cervical tissue. There is no danger of injury to the bladder at this point as it never descends this low on the cervix even in the most extensive cystocele. If the cervix is badly lacerated or markedly hypertrophied or elongated a trachelorrhaphy or circular amputation should be performed before undertaking the next step of this procedure.

Step 2 (Fig 2). At the completion of such an operative procedure on the cervix, the upper cut edge of the vaginal mucous membrane is held with

tooth forceps and a blunt pointed dissecting scissors is gently inserted to separate the bladder from the overlying fascia attached to the anterior vaginal wall. This maneuver is easily accomplished by spreading the blades of the dissecting scissors, the blunt point being inserted well up to within 1 centimeter of the level of the urethra. The dotted line indicates the next incision, which divides the anterior vaginal wall and fascia up to a centimeter of the urinary meatus.

Step 3 (Fig 3). This median longitudinal incision through the vaginal wall and fascia is accomplished with very little bleeding and no danger to the bladder, which in this line of cleavage is very

CLINICAL SURGERY

FROM THE SERVICE OF HAKOLD BRUNN MOUNT ZION HOSPITAL

THE INTERPOSITION OPERATION WITH STERILIZATION

FRANKLIN I. HARRIS, M.D., F.A.C.S., San Francisco, California

THE revival of interest and excellent results reported recently in the treatment of cystocele and prolapse by the operation of interposition has prompted the writer to offer a detailed account of the modern technique of this procedure, originally described by Watkins and Wertheim. This valuable operation early fell into disrepute because of unjustified criticisms.

The occurrence of pregnancy occasionally in an interposed uterus in which the operator had failed to take proper precautions against such a complication was publicized as a condemnation of this operation. The appearance of an elongated hypertrophied cervix through the introitus following interposition was charged as a failure to cure prolapse, whereas the failure was chargeable to the operator for not recognizing the necessity of combining cervical amputation with interposition in such a case. The attempt to perform this procedure in small, contracted vaginas led to technical difficulties and disappointment in the method. Today, the sound basic principles enunciated by Watkins and Wertheim are receiving the recognition they so justly deserve by surgeons who have followed the proper indications and carefully developed a safe and simple technique in applying these principles in the treatment of cystocele and prolapse.

Cattell and Swinton report satisfactory results from the Lahey Clinic. Houston Everett, reporting from Johns Hopkins Hospital, finds this method safer and more satisfactory than vaginal hysterectomy, and Phaneuf finds it to be a very satisfactory method of treating uterovaginal prolapse in a series of 188 cases.

During the past 15 years this procedure has been used at the Mount Zion Hospital, San Francisco, in a series of 57 private and service patients who have been available for satisfactory follow-up examinations from 2 to 7 years following the operation. The results have been highly satisfactory, both from the functional and anatomical viewpoint. There have been no operative deaths in this series and but one recurrence. Eighteen of these

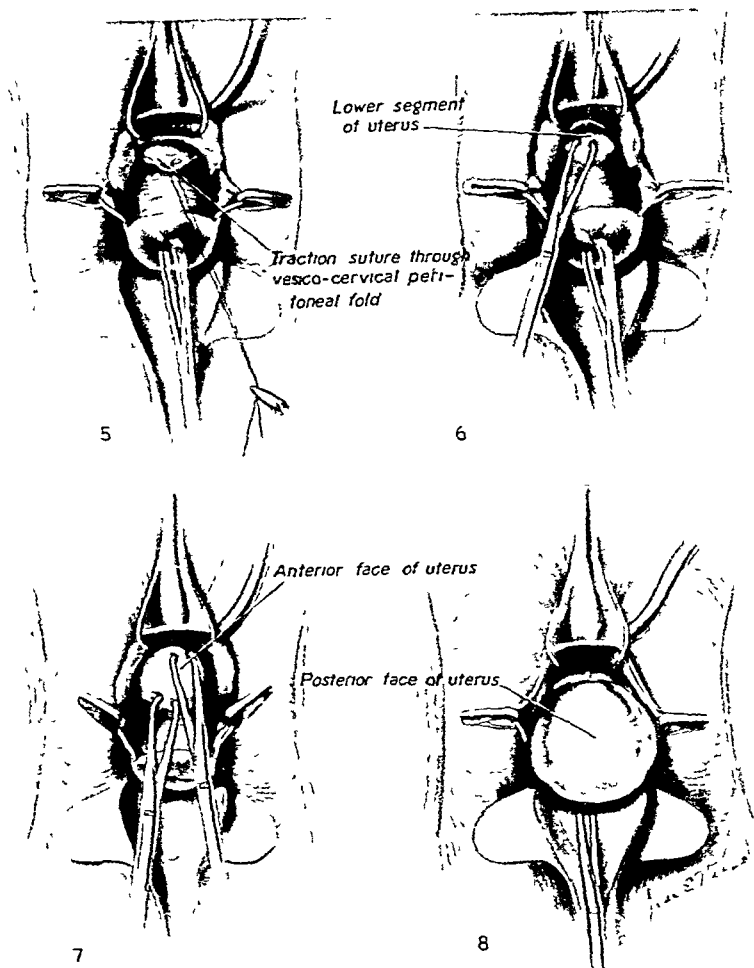

patients have been in the childbearing age; most of them in the early thirties and were sterilized according to the technique herein described. No pregnancies occurred subsequently. Contrary to the opinion expressed by many writers, I do not believe that this procedure should be reserved for only those women at or past the menopause. Young women with large families can by this method be conveniently sterilized without the necessity of abdominal section.

The indication for this procedure has been the presence of a large cystocele, with or without a moderate degree of prolapse, in patients whose uterus was not otherwise diseased or unduly enlarged. In complete prolapse, or in prolapse associated with a diseased uterus, vaginal hysterectomy has been preferred. Chaffin, who performs this procedure in all cases of cystocele as well as first and second degrees of uterine prolapse, emphasizes the contra-indication of previous pelvic laparotomy. When such laparotomy has been done for ligament shortening or pelvic inflammatory disease, adhesions may prevent the delivery of the uterus necessary for successful interposition.

Subarachnoid anesthesia has been used in the majority of these cases. If general anesthesia is used, either cyclopropane or nitrous oxide is the anesthetic of choice.

TECHNIQUE

Step 1 (Fig. 1). After the usual vaginal preparation a mushroom retention catheter is placed in the bladder and clamped. It is attached to a towel on the patient's abdomen, where it remains throughout the entire operation. This serves as a later guide to identification of the urethra. A heavy weighted vaginal speculum is inserted to hold the posterior vaginal wall toward the sacrum. The cervix is grasped with a strong tenaculum and turned downward, exposing the cystocele and completely inverting the anterior wall of the vagina, which is maintained in this position by moderate tension on the tenaculum. A transverse incision of approximately 2 centimeters is made through the mucous membrane of the anterior vaginal wall

Figs 5 to 8

Step 8 (Fig. 8). The uterus is now acutely ante-flexed and drawn out of the vagina so that only the posterior wall comes into view. The adnexa may now be visualized or palpated. If the patient is in the childbearing age, sterilization must now be performed.

Step 9 (Fig. 9). The sterilization procedure is relatively very simple and absolutely dependable in this technique. Ligatures of No. 1 chromic catgut are placed respectively 1 and 1½ centimeters from the cornual insertion of the tubes. The tubes are divided between these two ligatures. In the illustrations is also shown the traction suture which may be used in place of the tenaculum if the uterus is extremely friable.

Step 10 (Fig. 10). The principle of sterilization in this technique is dependent on the proximal portion of the tubes being ultimately bound in scar tissue outside of the peritoneal cavity. The two proximal ends of the tubes should be isolated from the distal ends by curving them forward on to the fundus and loosely approximating them to each other in this position.

Step 11 (Fig. 11). The uterus is rotated slightly to permit the distal ends of the tubes to drop back into the peritoneal cavity. The traction suture on the vesical edge of the cut peritoneum is utilized again to identify this plica of peritoneum preparatory to closure of the peritoneal cavity. If a narrow abdominal pack has previously been placed

loosely attached. Difficulty will be encountered if an attempt is made to develop a line of dissection between the fascia and the anterior vaginal wall. Such a step is not necessary and the separation of the two layers off the bladder by the method described is simple, safe and effective. The Allis clamps are attached to each of the lateral flaps of the vaginal wall and held under moderate tension by the assistants. The bladder is dissected free by sharp and gauze dissection laterally from these flaps down to the cervix. This lateral separation should be carried far enough to permit the excess of vaginal wall to be resected at the completion of the operation. In the midline, just in front of the cervix there is a fairly firm attachment by strong connective fibers between the bladder and the cervix. These fibers are called the vesicocervical or uterovesical ligament and must be divided with scissors before the bladder can be rolled off the cervix. They are held up by forceps and can be seen to be different from the bladder wall. There is danger at this point of cutting into the bladder if these fibers are not properly identified. The indwelling catheter can be used as a guide if there is any doubt as to the identification of the bladder wall from the vesicocervical ligament.

Unless the bladder is completely freed up and rolled off the cervix in this manner so that it can later lie smoothly and evenly on the posterior superior aspect of the uterus, urinary complications might follow the operation. These complications result from sacculation produced in a bladder which is unevenly compressed by the interposed uterus.

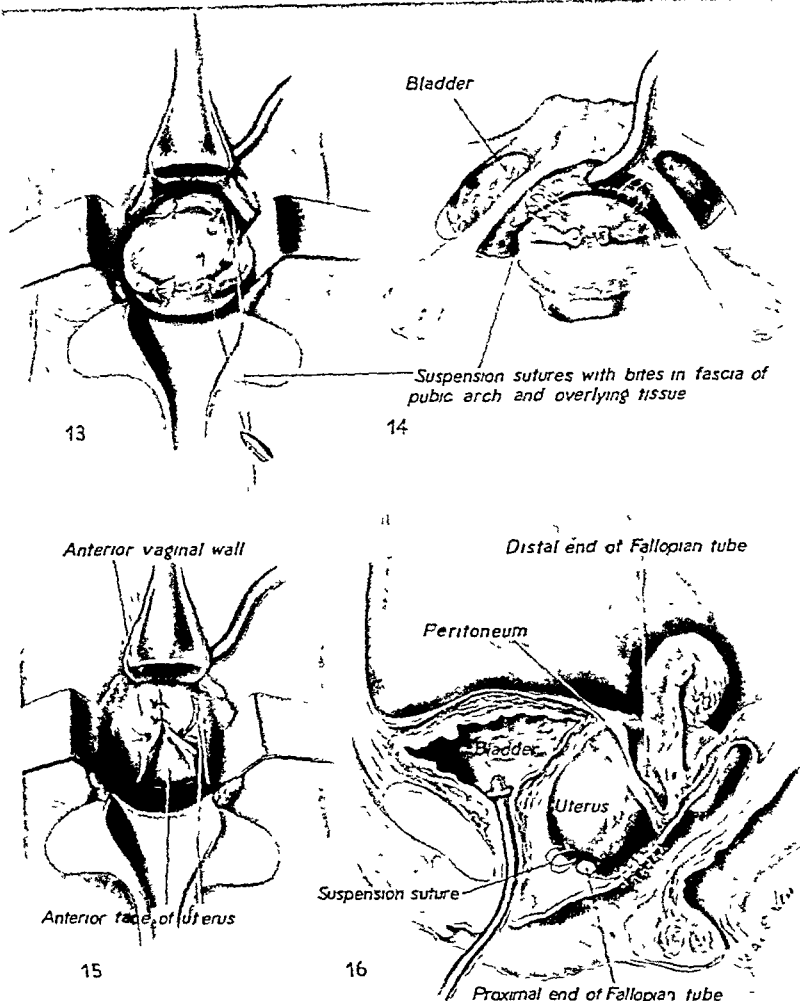

Step 4 (Fig. 4) If a clean dissection of the bladder from the lateral vaginal wall has been made and the vesicocervical ligament cut, the next important step can be easily accomplished. With a thin layer of gauze covering the gloved finger the bladder can now be gently rolled up from its descent on to the anterior wall of the cervix. This blunt gauze dissection is carried well upward in order to expose the peritoneum which at this point is called the vesico-uterine or vesicocervical fold of the peritoneum. Some difficulty may be encountered in this part of the operation if the proper plane of dissection has not been obtained. If sharp dissection has been necessary to free the bladder off the cervix there may be a tendency, in order to avoid cutting into the bladder to carry the dissection too deep into the cervix. As the dissection is carried higher and higher it will be entering a false plane lying between the peritoneal pouch and the uterus and the operator will vainly hunt for the peritoneal fold. Gauze

dissection after preliminary sharp dissection of the restraining fibers of the vesicocervical ligament usually establishes the proper plane of cleavage although in some cases the scissors may be needed to cut some resistant fibers off the bladder wall from the upper part of the cervix. If the operator frequently palpates the indwelling catheter during these steps, there will be little need of seeking a deeper or false line of dissection in an attempt to protect the bladder from injury. The blunt dissection described usually follows the line of least resistance and clearly exposes the peritoneal pouch between the bladder wall and the vesical peritoneum.

Step 5 (Fig. 5) A narrow retractor is now placed anteriorly to hold the freed up bladder toward the symphysis and to expose the peritoneal fold. This fold may often be identified by direct vision in this manner and must always be recognized by touch. If the finger presses on this fold toward the uterus and is moved back and forth the two smooth peritoneal surfaces can be distinctly felt moving on each other. A traction suture of No. 1 plain catgut is now placed through the anterior part of the peritoneal wall which is then held up and incised with scissors. As the peritoneum is opened a small amount of peritoneal fluid may escape which may give the operator the impression it is urine and that he has entered the bladder. However, by further exploration with the finger in the opening the smooth fold of the fundus of the uterus can be felt and perhaps some omentum. If the patient is straining small bowel or omentum may be forced through the peritoneal opening and it may be necessary to insert a narrow abdominal pad to keep the viscera back. This annoying complication seldom happens if spinal anesthesia is used, and the patient is in moderate Trendelenburg and a fairly high lithotomy position.

Step 6 (Fig. 6) The traction suture on the vesical edge of the opened peritoneum is now held anteriorly thus exposing the anterior wall of the lower segment of the uterus. A single hook tenaculum clamps this portion of the uterus and gently draws it forward. Care must be taken not to tear the uterus by rough traction on the tenaculum as it leads to troublesome bleeding.

Step 7 (Fig. 7) As the uterus is drawn forward a second tenaculum is applied at a higher point on the anterior surface of the uterus. Occasionally the uterine wall is so soft that the tenaculum tears out even with slight traction. In such cases a double heavy mattress suture may be placed deep into the uterine wall so as to serve as a traction suture in order to draw the uterus out of the peritoneal cavity.

Figs 13 to 16

fixation sutures described by Crossen for suspending the uterus in its new position, are used. They are entirely buried and have proved very satisfactory. I believe they are largely responsible for the absence of recurrences and the firm fixation of the uterus to the pubic edge. No 3 chromic catgut is used as there may be considerable tension on these sutures. A bite is first taken high up at the angle of the pubic arch, a hemostat first being placed on the short end of the suture. This bite of the needle is into tissues that have a firm attachment to the pubic bone. The needle is passed through these tissues, then carried deep into the fundus of the uterus and back to take a second

firm bite into the fascia-like tissue of the pubic arch, and carried by the same hemostat holding the short end of the suture. A similar suture is placed on the other side. If both of these suspension sutures have been satisfactorily placed, the hemostats are removed and, by gentle traction on the two ends of the suspension sutures, the uterus is slowly rotated anteriorly as the anterior bladder retractor is removed. The fundus of the uterus is then placed snugly under the pubic arch exerting some pressure on the urethra. The degree of pressure on the urethra can be estimated before the final step of tying the suspension sutures is completed.

Figs 9 to 12

in the peritoneal cavity it is now removed. The peritoneum is attached to the posterior wall of the body of the uterus by two interrupted catgut sutures closing the peritoneal cavity, and making the operative area entirely extraperitoneal. In the illustrations the vesical flap appears fixed somewhat too high on the posterior aspect of the uterus. It is important that this suture line be placed low at approximately the level of the junction of the cervix and the body of the uterus.

Step 12 (Fig 12) The fundus of the uterus is rotated toward the peritoneal cavity thus exposing the anterior wall. It may occasionally be possible easily to demonstrate the cut uterine edge of the peritoneal fold by this maneuver and to suture

it with two or three interrupted catgut sutures to the anterior wall. However this step is not absolutely essential and may be omitted if technically difficult.

Step 13 (Fig 13) In order to fix permanently the fundus of the uterus under the pubic arch so as to act as a shelf for the replaced bladder Watkins originally described the crown suture which passed through the vaginal mucosa from outside included the fundus of the uterus and passed out the other side of the vaginal mucosa, the knot finally being tied above the vaginal mucosa after its closure. This suture tends to produce painful swelling and occasional pressure necrosis. In this technique two suspension sutures, similar to the

HALLUX VALGUS

WALTER I. GALLAND, M.D., and HENRY JORDAN, M.D., New York, New York

IN 1904 W. L. Keller in the *New York Medical Journal* published a description of an operative procedure for the correction of hallux valgus. This procedure involved the removal of the proximal articular end of the first phalanx together with the prominence on the internal aspect of the first metatarsal head. At the time of this publication 3 cases were reported with satisfactory results. This operation has been described in American literature from time to time, but has never attained wide popularity.

Abroad during the last 10 or 15 years, there has been a rediscovery of the Keller operation, and it has become particularly associated with the name of Brandes, who has been one of the chief exponents of the method. Altogether about 750 cases have been reported with results so satisfactory that by many authorities this procedure is recommended as the preferential one.

In 1930 Timmer stated that reports of 25 different methods for the operative correction of hallux valgus have been published. This estimate is surely conservative. The great number of methods is indicative of the unsatisfactory state of the operative methods in vogue.

In view of the favorable experience on a larger series of cases abroad of one of the authors (H. J.) with the Keller-Brandes type of procedure, we have determined to evaluate the comparative merits of this operation, for we feel that the results in a small series of cases would warrant recording.

We would first discuss briefly some of the anatomical and pathological aspects of hallux valgus which have a direct bearing upon the operative relief of this condition. Hallux valgus is usually not a congenital but an acquired deformity. Most of these deformities are caused by mechanical conditions which result from a pes plano-valgus transverso-planus. The valgus position of the heel and tarsus is the original deformity in the causative train. The pressure of the foot on the ground while the patient walks causes the abduction of the forefoot and the supination and dorsiflexion of the first metatarsal bone and great toe. The falling of the metatarsal arch is only relative. As a matter of fact the shifting dorsally of the first metatarsal head creates what appears to be a plantar prominence of the second, third, and fourth metatarsal heads. By this mechanism the

first metatarsal bone is forced into marked abduction, and this abducted position is not a primary but a secondary deformity. Due to the tension of its tendons, the great toe cannot follow this abduction of the first metatarsus, consequently it deviates and a subluxation of the metatarsophalangeal articulation occurs. Secondary productive arthritis in the first metatarsophalangeal joint may follow.

According to Hohmann a second group exists, in which the metatarsus varus is a part of a varus position of the entire foot. This type of case is decidedly in the minority, and the static group first mentioned most certainly comprises the vast majority of all cases of hallux valgus.

Inasmuch as, according to our conception of hallux valgus, the deformity is initially due to a valgus or plano-valgus, it is obvious that any operative correction can be effective only if the local causative deformity is also corrected. The correction of the entire foot before entering upon the operative phase of the treatment, is of the greatest importance in order eventually to avoid recurrence. We therefore believe that a rigid or spastic flat foot should be manipulated and corrected before an attempt is made to overcome the hallux valgus deformity. Following the hallux valgus operation, the normal position of the entire foot and correct static conditions must be maintained by means of adequate foot plates.

The Keller-Brandes operation is indicated in cases in which the hallux valgus deformity disables the patient and interferes with his work. Patients in this group who desire to be cured radically and rapidly and who wish to return to their work as soon as possible are the proper subjects for this procedure. Those patients who are mainly interested in the immediate cosmetic result of the operation should not be handled according to this method, inasmuch as full control of the great toe is re-established only after a period which must be measured in months.

TECHNIQUE OF OPERATION

The pre-operative preparation of the foot is essential, inasmuch as the skin of this area is grossly contaminated. We would particularly advise that the foot should be closely examined for evidence of fungus infections, and if such are found, a rigid pre-operative treatment should be

Step 14 (Fig 14) The suspension sutures on either side are tied, thus approximating the fundus of the uterus under the pubic arch and supporting the bladder and urethra. The new position of the urethra with the pressure on it of the uterine fundus is usually sufficient to cure the incontinence associated with the urethrocele found in the majority of cases of cystocele and prolapse. In severe cases of incontinence, a preliminary reefing of the extrinsic urethral muscle is performed as an additional step early in the operation. This is best done after the exposure of the bladder in Step 3 when the torn muscle fibers may be easily identified before the bladder is freed up and reduced into the abdominal cavity.

Step 15 (Fig 15) Closure of the anterior vaginal wall over the uterus completes the operation. If there is an excess of vaginal mucous membrane, excision of this excess on either flap is first performed. The flaps are then approximated in the midline with interrupted No. 2 chromic sutures each suture taking a bite into the wall of the underlying uterus. Closure is completed by approximating the lower ends of the anterior vagina to the anterior lip of the cervix.

Step 16 (Fig 16) In practically all cases a complete repair of the relaxed pelvic floor is done by one of the standard methods of perineorrhaphy and is essential to a successful result. Sagittal section shows the uterus now acting as a shelf which supports the urethra and bladder. The distal ends of the cut fallopian tubes are within the peritoneal cavity, whereas the proximal portions are entirely extraperitoneal and effectively prevent impregnation.

The immediate postoperative course of the interposition case is extremely satisfactory. There is practically no shock to the procedure and symptoms of abdominal distention are never present. The advantages of this procedure over laparotomy combined with vaginal plastic procedures are seen at once in the smooth convalescence. The patient has been saved the prolonged anesthesia of two separate operative procedures and pulmonary complications are proportionately lessened. The additional operative risk incident to any laparotomy is removed when the entire procedure can be done through the vagina.

Opponents of the interposition operation have stressed the high incidence of bladder complications such as dysuria and frequency. As previ-

ously pointed out in the technique, such a complication, if permanent, is due to faulty technique in failing to free up the bladder completely so that it can lie smoothly on top of the uterus when the operation is completed. The symptom of urinary incontinence in varying degrees which practically all of these patients with cystocele and prolapse present is completely cured by well performed interposition which changes the direction of the urethra and gives the urethral floor the support of the uterine fundus. Reefing of the extrinsic urethral muscles is seldom necessary, although it has been used in those few cases which have shown marked pre-operative incontinence.

The retention catheter remains in the bladder for a period of from 4 to 7 days following the operation. During the first 48 hours it is opened every 6 hours. Following this period the urine is released at 8 hour intervals and the patient is given daily bladder irrigations of 1,300 metapphen solution. When the catheter is removed the patient is usually able to void spontaneously. An occasional patient may have symptoms of a residual cystitis which responds to treatment during the first few weeks following surgery.

The average hospital stay of these patients is from 14 to 16 days.

SUMMARY

A description of the technique of the interposition operation based on an experience with 57 cases is given. This procedure has been used with excellent anatomical and functional results in the treatment of cystocele and moderate degrees of prolapse. It has been used in women during the childbearing age with the additional procedure of sterilization and has been found to have less morbidity and mortality than laparotomy combined with vaginal plastic procedures in the treatment of this condition.

Fig 3 Left, Case 5, before operation Right, Case 5, after operation

sequent osteotomy The phalanx is now cut transversely with a bone cutting forceps The section must be made smoothly It is desirable to remove not less than the proximal two-thirds of the phalanx The removal of the bone is facilitated by the insertion of a sharp bone hook into the distal end of the proximal fragment to be used as a tractor thus exposing the plantar and internal aspects of the phalanx, so that by cutting with a scissors close to the bone, the fragment can be safely dissected and removed

The removal of the proximal two-thirds of the proximal phalanx leaves a large wide open wound, in which any potential points of bleeding can be easily recognized and ligated The fascia which usually at this stage can be found curled back laterally under the extensor tendon is sutured in place by five or six interrupted chromic sutures A few subcutaneous plain or chromic gut sutures are used, and the skin is closed with absorbable or non-absorbable material, according to the operator's inclination (Fig 2).

The aspect of the toe immediately after closure

is apt to be somewhat disconcerting to the operator performing this procedure for the first time. The digit is hypermobile, and appears simply to hang upon a collar of skin. It is of course easy to bring the toe in perfect alinement with the first metatarsal bone It is impossible for any tension to exist after this extensive resection The foot is now immobilized in plaster of Paris with the great toe held in the corrected position This may be achieved by means of a plaster-of-paris splint applied to the sole of the foot It is not desirable to remove all of the tension from the extensor and the flexor tendons, and it is equally desirable to avoid skin creases which form due to the relaxed condition of the integument of the toe following the bone resection In order to avoid undue skin and tendon relaxation and to obtain a good cosmetic result as quickly as possible, it is desirable to keep the great toe in extension or in traction while the foot is immobilized. This may be done by means of a suture through the tip of the great toe, or through its toe nail, and attaching this suture under moderate tension to a post, incor-

Fig. 1 Operative procedure

entered upon until this infection is entirely under control. Even in feet not infected with fungi, it is advisable to provide several days of pre operative cleansing of the feet in order to remove the abundant contamination which has been ground into the skin in the act of walking.

We prefer to operate on a bloodless field provided by the careful application of an Esmarch bandage. The use of an Esmarch bandage greatly facilitates the operation and saves time. General anesthesia is perhaps somewhat preferable to local anesthesia as there is no local trauma which might impair the nourishment of the tissues and impede the healing process. Avertin narcosis is often sufficient and, if supplemented with nitrous oxide gas and oxygen, entirely adequate. Of course if patient prefers or his general condition does not permit use of general anesthesia local anesthesia with $\frac{1}{2}$ to 1 per cent procaine solution with adrenalin gives satisfactory results.

An incision 2 to 3 inches in length is made on the dorsum of the foot beginning over the distal third of the first metatarsal bone and curving laterally around the head of the bone to the distal third of the proximal phalanx (Fig. 1). The skin is dissected from the underlying tissues and is retracted so that ample exposure is provided. Instead of using retractors we have found it most convenient to use retracting sutures which are placed at the lateral and medial skin edges and tied under the plantar aspect of the foot. Before tying these sutures gauze pads are placed under them at the skin margins. As these sutures are

Fig. 2 Appearance before closing

tied the skin edges are retracted over the gauze pads and it is no longer necessary to employ an assistant for retraction purposes and at the same time through the mediation of the gauze pads, the wound is protected from skin contamination. The fascia is now incised longitudinally and the extensor hallucis tendon is retracted laterally. The prominence of the first metatarsal head is now exposed without removal of the overlying bursa. The capsule of the first metatarsophalangeal articulation is incised transversely, and upon exposure of the articular end of the metatarsal the groove which separates the exostosis from the head of the first metatarsal bone appears. A chisel is now driven into this groove in the direction of the longitudinal axis of the first metatarsal bone and the entire exostosis is thus removed. Any osteophytes on the dorsal and lateral aspect of the first metatarsal head are removed and the entire head of the bone is carefully smoothed. The proximal two-thirds of the proximal phalanx are now exposed by means of blunt dissection with a periosteum elevator. It is well to separate the bone around its entire circumference particularly on its plantar aspect in order that the flexor hallucis tendon should not be injured in the sub

Fig 3 Left, Case 5, before operation Right, Case 5, after operation

sequent osteotomy. The phalanx is now cut transversely with a bone cutting forceps. The section must be made smoothly. It is desirable to remove not less than the proximal two-thirds of the phalanx. The removal of the bone is facilitated by the insertion of a sharp bone hook into the distal end of the proximal fragment to be used as a tractor thus exposing the plantar and internal aspects of the phalanx, so that by cutting with a scissors close to the bone, the fragment can be safely dissected and removed.

The removal of the proximal two-thirds of the proximal phalanx leaves a large wide open wound, in which any potential points of bleeding can be easily recognized and ligated. The fascia which usually at this stage can be found curled back laterally under the extensor tendon is sutured in place by five or six interrupted chromic sutures. A few subcutaneous plain or chromic gut sutures are used, and the skin is closed with absorbable or non-absorbable material, according to the operator's inclination (Fig. 2).

The aspect of the toe immediately after closure

is apt to be somewhat disconcerting to the operator performing this procedure for the first time. The digit is hypermobile, and appears simply to hang upon a collar of skin. It is of course easy to bring the toe in perfect alignment with the first metatarsal bone. It is impossible for any tension to exist after this extensive resection. The foot is now immobilized in plaster of Paris with the great toe held in the corrected position. This may be achieved by means of a plaster-of-paris splint applied to the sole of the foot. It is not desirable to remove all of the tension from the extensor and the flexor tendons, and it is equally desirable to avoid skin creases which form due to the relaxed condition of the integument of the toe following the bone resection. In order to avoid undue skin and tendon relaxation and to obtain a good cosmetic result as quickly as possible, it is desirable to keep the great toe in extension or in traction while the foot is immobilized. This may be done by means of a suture through the tip of the great toe, or through its toe nail, and attaching this suture under moderate tension to a post, incor-

Fig. 4 Case 6 Anteroposterior and lateral view of right foot approximately 1 year after operation

porated in the plaster of Paris dressing. The traction should be so arranged as to pull the great toe in a position neutral between abduction and adduction and in slight plantar flexion. Traction can usually be removed at end of a week. For the first few days after the operation the foot of the patient's bed should be elevated about 8 inches. This adds materially to the postoperative comfort.

As a rule, the postoperative temperature reaction is very slight and a normal level is achieved 3 or 4 days following the operation. After 5 or 6 days the patient may be out of bed in a wheel chair, and it is possible to discharge patients on whom a unilateral operation has been performed after 1 week, at this time weight bearing may be instituted in the plaster. The plaster splint is removed 8 or 10 days following operation and an elastoplast strapping is applied from the toes to the knee. Particular attention is given to the remodelling of the forefoot in order to restore the metatarsal arch and the first and fifth metatarsal bones are kept in an adducted position. Plaster casts can be made for the preparation of proper foot braces in about 2 weeks after operation. The elastoplast strapping should be applied for at least 3 weeks. Some physical therapeutic after care is desirable, particularly in older patients with poor circulation.

The majority of patients in whom only one foot has been operated upon will be able to return to work about 2 to 3 weeks after operation. Of course, it must be expected that at this time the function will not be even approximately normal. The full benefit of the operation does not become apparent until a period of 6 months has elapsed.

The operative correction of hallux valgus must be considered with the primary view of preserving or restoring with a minimum of risk, the normal physiological mechanism of the foot. Any operative procedure which seriously impairs the function of either the transverse or of the longitudinal arch of the foot is erroneous in its conception. We feel that the Keller Brandes procedure restores the normal mechanism of the foot with a minimum of risk to the patient.

By effectively removing all deforming tension on the deviated hallux this operation readily permits the proper alignment of the hallux and of the metatarsus primus varus. There is effective restoration of the contour of the anterior metatarsal arch and the integrity of the longitudinal arch is in no way impaired.

It has been urged that the operation may produce marked metatarsophalangeal arthritis. The risk of this complication is, we think, far less than in any other of the generally accepted procedures with the possible exception of the major operation. This latter, however, entirely destroys the inner pillar of the anterior and the anterior pillar of the longitudinal arches. If the advice of Brandes is followed and fully two-thirds of the proximal phalanx is removed a potential joint space of such width is provided as to render subsequent painful articular friction highly improbable.

It has been suggested that the cosmetic result of shortening the great toe is an undesirable feature of the operation. To this criticism we would urge that in the average case of bunion the great toe is unduly long so that the shortening of this digit is in most cases, entirely desirable. We would also urge that restoration of painless function and not cosmetic considerations should be the prime objective of the bunion operation and this objective we believe is most consistently fulfilled by the Keller Brandes operation.

A feature of the operation which may be urged, is the factor of safety which is provided in the occasional case in which, despite the most meticulous precautions, the wound becomes infected. The cavity which is left by the removal of the proximal two thirds of the proximal phalanx is readily drained through the operative incision, and the simple early opening of a few sutures converts the zone of infection into a single, effectively

Fig 5 Left, Case 7, before operation Right, Case 7, after operation

drained pocket. There is no necessity for multiple drainage incisions and the diastasis between the component bones of the articulation again renders the advent of arthritis less probable and absolute ankylosis is certainly not to be anticipated, even after a fairly severe infection.

The operation must also be considered from its applicability to conditions allied with, or frequently complicating, hallux valgus. In those cases in which hallux rigidus is present with or without a valgus position of the great toe, this procedure is spectacular in its efficacy. The complication, sesamoiditis, which so often attends deformations of the forefoot can be effectively coped with during this procedure. The removal of the phalangeal section makes the approach to the sesamoids a simple task and the removal of these ossicles, if desirable, is effected readily.

During the past 2 years 11 of our patients have been operated upon by the Brandes-Keller procedure for hallux valgus or hallux rigidus, in 4 cases on both feet simultaneously, thus giving a total of 15 hallux valgus operations of this type.

CONCLUSION

1. The Keller-Brandes operation for hallux valgus (or rigidus) in which the proximal two-thirds of the proximal phalanx of the great toe, together with any attending exostosis is removed, affords a simple and safe method for coping with all of the deforming influences producing this deformity.

2. The period of postoperative disability is shorter than that of the average exostosectomy.

3. The ultimate cosmetic and functional results are gratifying both to the patient and to the physician.

4. The postoperative morbidity is slight.

INSTRUMENTAL DILATATION OF THE PAPILLA OF VATER

Experimental and Clinical Observations

ROBERT ZOILINGER, M D F A C S CHARLES D BRANCH, M D and
ORVILLE T BAILEY M D Boston Massachusetts

THE indications for exploring the common bile duct in operations for cholelithiasis have been fairly well established. Statistics (20) show that calculi are found in the common bile duct in approximately 20 per cent of all cases; if exploration of the common bile duct is performed in as much as 40 per cent of such operations. Various methods have been recorded for exploring the common bile duct in order to remove calculi and to determine the patency of the papilla of Vater. In some instances, these steps are followed by dilatation of the papilla. Those who favor this further procedure believe that it promotes the passage of calculi and debris not removed by careful scooping and irrigation of the bile ducts. They feel that a more satisfactory drainage of bile into the duodenum will also be maintained.

It has been our custom to follow the method of Cheever in this operation. This involves the passage into the common bile duct of a No. 10 F soft woven catheter, which is the size of the average papilla in the human being. Saline is injected through the catheter to establish the patency of the ampulla by the visible filling of the duodenum. The injection of saline is continued while the catheter is slowly withdrawn in order to dislodge and force overlooked calculi into the opening of the common bile duct. Following this catheters of size No. 16 F are passed but rarely those of larger caliber. Allen has recommended the use of Baké's metal dilators for extensive dilatation of the papilla of Vater even up to the size of the common bile duct itself so as to permit overlooked calculi to escape. Allen and Wallace and Baké have recorded instances of the passage of calculi in the stools following such dilatation. These apparently had been overlooked at the time of operation. We have not encountered any serious complication directly attributable to the catheter method of dilatation of the papilla. However, the possibility and dangers of duo-

denal reflux have been emphasized (9, 16). Lahey has reported 2 deaths following the use of Baké's dilators which he states were the result of over dilatation of the papilla of Vater. All of the various methods of dilatation accomplish the important step of making certain of an unobstructed communication with the duodenum. We have considered whether greater dilatation of the papilla is of sufficient value to the patient to overshadow the dangers associated with extensive stretching of its tissues. In order to study this problem experiments on dogs were carried out to determine both early and late effects of the methods of dilatation on the papilla of Vater. We believe that the anatomic details in this region are sufficiently similar to allow the application of data obtained from dogs to patients. The recent study of Boyden compares this region in man and various animals. In the dog the pancreatic duct and the common bile duct open separately into the duodenum but there is a two layered musculus proprius comparable to that of man.

EXPERIMENTS

Experiments were carried out on more than 50 dogs to study the effects of various degrees of dilatation on the papilla of Vater, liver, and extrahepatic bile ducts. In each dog the papilla was dilated transduodenally by one of the two previously mentioned methods. This was done with and without cholecystectomy and at short and long intervals following removal of the gall bladder. Gross and microscopic studies were made from normal controls. The caliber of the papilla in normal dogs obviously varies with the size of the animal but we have accepted a No. 20 F as the average in the dogs in this laboratory (Table I). Reports (3, 8, 11, 12, 17, and 18) have indicated that within 120 days cholecystectomy is followed by spontaneous dilatation of the biliary duct system. In order to determine the amount of this dilatation alone cholecystectomy without dilatation of the papilla of Vater was performed on 6 dogs. After 4 months the size of the papilla had increased to No. 14 F. In the

TABLE I

Type of experiment	No. of animals	Survival days	Ampulla dilated to	Size of ampulla
Control				10 F.
Cholecystectomy	6	120		14 F
Cholecystectomy and catheter dilatation	7	96	18 F	10 F
Cholecystectomy and Bakés dilatation	5	63	17 F	12 F
Catheter dilatation	5	135	21 F	10 F
Bakés dilatation	3	120	23 F	10 F
Dilatation and cystic duct drainage	4	92	21 F	11 F
Dilatation 200 days after cholecystectomy	6	100	20 F	12 F
Acute experiments	15	1-28	22 F	

first series of experiments, an attempt was made to pass catheters through the stump of the cystic duct. This proved a difficult procedure in the dog, for it was impossible to secure considerable dilatation of the papilla without tearing the common bile duct. Because of this, transduodenal dilatation was used. In 7 dogs, cholecystectomy was followed by dilatation of the papilla with catheters by the transduodenal approach to an average size of No. 18 F. These dogs were examined on an average of 96 days following the operation, and it was found that in all of them the papilla had returned to normal size. The Bakés metal dilators were used in a group of 5 dogs to dilate the papilla to sizes averaging No. 17 F. Sixty-three days following operation, autopsy showed the papilla to have returned to approximately normal measurements, in this instance No. 12 F.

Since cholecystectomy alone produces an enlargement of the papilla of Vater, the effect of transduodenal dilatation without cholecystectomy was studied. In 5 dogs the papilla was dilated by catheters and in 3 dogs by the use of metal dilators, to No. 21 F. and 23 F., respectively. After a period of at least 4 months, the average measurement of the papilla was found to be No. 10 F.

In a group of 4 dogs, an attempt was made to simulate the method used in the human being by removing the gall bladder and draining the common bile duct by a catheter introduced through the cystic duct. The papilla was then dilated by the transduodenal method, the Bakés dilators being used, to an average size of No. 21 F. These dogs were sacrificed after a period of 3 months, and it was found that the papilla had returned to No. 11 F. in caliber.

Fig. 1. Photomicrograph of the papilla of Vater 3 days after dilatation with Bakés instrument. The lumen, at the right, is filled with fibrin and leucocytes. The mucosa is interrupted and shows acute inflammatory reaction. $\times 90$.

The papilla of 6 animals was dilated transduodenally on an average of 200 days after removal of the gall bladder. This was done to determine the effects of dilatation on a pathological biliary system. Graded catheters were passed through the papilla to an average size of No. 20 F. The average size of the papilla 100 days later was only No. 12 F. These experiments indicate that the papilla after extensive dilatation returns to a size smaller than that after cholecystectomy alone.

In addition, a study was made of the immediate effects of dilatation. The papilla was dilated to a No. 22 F. in a series of 15 dogs. These were sacrificed at intervals varying from 1 to 28 days. Gross examination at the time of sacrifice showed, in the first week, that there was a large, edematous papilla protruding into the lumen of the duodenum. No attempt was made to measure the actual size, to obtain microscopic sections which had had no other trauma than that occurring at the original dilatation.

MICROSCOPIC STUDIES

Histologic examination of the papilla of Vater showed that the early changes in the region of the papilla were those of hemorrhage and acute inflammation. In the specimens examined 1 to 3 days after dilatation, the continuity of the epithelium was broken in many places and these intervals were filled with fibrin and polymorphonuclear leucocytes. This exudate was so extensive as to fill the lumen almost entirely (Fig. 1). In addition, there were rather large areas of hemorrhage in the surrounding tissues. The portions of mucosa not eroded showed edema and infiltration with polymorphonuclear leucocytes.

INSTRUMENTAL DILATATION OF THE PAPILLA OF VATER

Experimental and Clinical Observations

ROBERT ZOLLINGER M D F A C S CHARLES D BRANCH M D and
ORVILLE T BAILEY M D, Boston Massachusetts

THE indications for exploring the common bile duct in operations for cholelithiasis have been fairly well established. Statistics (20) show that calculi are found in the common bile duct in approximately 20 per cent of all cases if exploration of the common bile duct is performed in as much as 40 per cent of such operations. In order to determine the amount of this dilatation alone cholecystectomy without dilatation of the papilla of Vater was performed on 6 dogs. After 4 months the size of the papilla had increased to No. 14 F. In the

Fig. 4. Chart showing the high initial rise and subsequent fall of the perfusion and ductal pressures in a patient in whom the papilla was dilated to 7 millimeters (Bakès)

of overlooked calculi it would seem that the perfusion pressure in these patients should be very low. Colp and his associates (7 and 10) have shown that any irritation to the papilla will cause temporary sphincteric spasm. From this it would seem that severe trauma to the sphincter from dilatation may cause prolonged spasm and thus prevent the passage of bile and calculi into the duodenum. Using methods described by Doubilet and Colp (10) and Butsch and McGowan we have followed in patients the pressure necessary to overcome the resistance of the sphincter immediately after dilatation of the papilla. As a control we inserted a catheter into the stump of the cystic duct, or into the common bile duct in other patients to determine the sphincteric resistance when there has been no manipulation. The resistance of the sphincter in a normal human individual is approximately 150 millimeters of water. To avoid the effect of morphine on the sphincter, readings were not taken until 6 or more hours following its administration. In a patient (Fig. 4) in which there had been dilatation of the papilla following choledochostomy to No. 22 F. (Bakès 7 mm) dilator, the sphincteric resistance was approximately 370 and the persistent ductal pressure was 300 on the day following operation. There was a fall in this sphincteric resistance over a period of several days, but it did not reach a normal level until approximately 4 days following operation. This is also true of the ductal pressure. The findings have been constant in 6 additional cases. In 3 patients in whom we have been able to introduce a very small catheter

Fig. 5. Chart showing absence of initial rise in perfusion and ductal pressures in a patient in whom choledochostomy was performed without dilatation of the papilla of Vater

through the stump of the cystic duct or directly into the common bile duct without manipulation of the papilla, the sphincteric resistance remained at about the normal limits, both on the day of operation and in the following days (Fig. 5). These findings are comparable to the microscopic study, which shows the lumen of the papilla filled with exudate and encroached upon by the edematous mucosa for several days after extensive dilatation of the papilla of Vater. From this it is suggested that in cases in which such dilatation of the papilla has been carried out, the sphincteric resistance does not fall below the normal limits during a period of 2 weeks after operation. As Doubilet and Colp have stated, the hydrostatic pressure caused by the bile does not act against the sphincter but forces the bile through the catheter, since less pressure is required to do this than to overcome the sphincteric resistance.

This resistance, as indicated by our experiments, following the extensive dilatation of the papilla of Vater in patients, suggests that such a procedure would be unwise if plastic operations are to be carried out on the common bile duct. The belief that incisions in the common bile ducts cannot be closed with safety after exploration of this structure may also depend on the increased ductal pressure resulting from morphine during the post-operative period, as shown by Walters and his associates (15 and 19). Irritation from the passage of instruments through the papilla of Vater may increase the pressure still further.

SUMMARY

An investigation has been carried out to determine the effect of extensive dilatation of the papilla of Vater to permit the escape of overlooked

Fig 2 The normal papilla of Vater of a dog showing intact layers of musculature separating the mucous membrane from the duodenal wall $\times 13$

At the end of a week the lumen of the papilla had reached approximately normal size and most of the exudate had disappeared. The continuity of the epithelium was almost completely restored. In the mucosal stroma there were many lymphocytes but polymorphonuclear leucocytic reaction was slight. There were many fibroblasts and some newly formed capillaries throughout the mucosa and in the layers of muscle ensheathing the papilla. Sometimes these even extended into the adjacent intestinal musculature for a short distance.

After one month considerable scar tissue had formed. This was in contrast to the normal dog's papilla, in which there is an intact investment of muscle about the terminal portion of the common bile duct (Fig 2). The scar tissue extended through the muscle at intervals and even involved the duodenal muscularis occasionally. The mucosal epithelium was complete but the glands appeared somewhat altered in outline and in the stroma about them were numerous lymphocytes and some plasma cells (Fig 3).

In the specimens of the papilla from dogs with a greater interval than a month between operation and autopsy, the only further changes were the progressive increase in the collagen of the scar tissue and its retraction. There was no further demonstrable alteration in the contour of the lumen of the duct. The lymphocytic reaction was not noticed after an interval of 2 months.

Sections of the liver were compared with con-

Fig 3 Papilla of Vater 1 month after dilatation of the papilla with Bakes instrument. Note the area of scarring and interruption of the musculature $\times 13$

trols from normal dogs and from dogs after cholecystectomy alone. Also in most experiments biopsies of the liver were obtained. We found no instances of marked hepatitis. In those dogs with strikingly dilated intrahepatic bile ducts there was some increase in connective tissue over that seen in controls but not to a great degree. Lymphocytes were only slightly more numerous about these ducts than in normal controls. The degree of normal variation seemed to us considerable.

CLINICAL APPLICATION

Autopsy statistics show that calculi are overlooked at exploration of the common bile duct in approximately one third of the cases (14). Because of this, any method which may tend to improve these results seems indicated. The experimental evidence tends to show, at least in animals, that the outlet of the duct is partially blocked by edema and the outpouring of exudate after extensive dilatation. Within a relatively short time the papilla returns to a size smaller than it would have been following cholecystectomy alone. Although such contracture seems a definite possibility, presumably on the basis of scar tissue formation, no serious late results have been recorded attributable to extensive dilatation of the papilla of Vater.

An estimate of the state of the papilla of Vater immediately after dilatation in patients was attempted by the use of the perfusion method, described by Butsch and McGowan. If the papilla is sufficiently dilated to permit the escape

CONDUCTION ANALGESIA IN ANORECTAL SURGERY

HARRY E. BACON, B.S., M.D., F.A.C.S., Philadelphia, Pennsylvania

ORIGINATED by Braun and modified by Allen, de Takats, and Werner as infiltration anesthesia, this method is termed conduction analgesia because the injections are made deliberately to analgesize the conducting pathways to the anorectum. Such planned procedure is in contrast to the random injections of infiltration or block analgesia. The term analgesia is used to signify abolition of pain sensation with no loss of cerebral functioning (4). Here the protopathic sensation is retained but the epicritic is lost. Since the conducting pathways are enveloped by the analgesic solution, the nerves are affected by diffusion (8).

This method of analgesia has been employed with excellent results in the surgical treatment of selected cases of internal and external hemorrhoids, prolapse, moderate procidentia, polyps, fissures, fistulas of the simple, straight variety, inflamed crypts, hypertrophied papillas, intranal ulcers, condylomas, and skin tags. In divulsion and removal of certain foreign bodies it may also be used. It is not applicable, however, when the extent of the disease process has not been determined before operation, when free suppuration is present, when there are present massive condylomas, multiple and complicated fistulas, or malignant tumors in which extensive surgical intervention is required and the growth is located in the region above the peritoneal reflection. These and such conditions as sequestration, dermoid cyst, stricture, procidentia recti, congenital anomalies, and imbedded foreign bodies, are better treated under general anesthesia or spinal analgesia.

PREPARATION

Two hours, and, again, one hour, before operation the patient receives by mouth 3 grains of sodium amytal or $1\frac{1}{2}$ grains of nembutal. At operation, the patient assumes the exaggerated lithotomy position, with the buttocks well over the edge of the table and a large pad under the sacral region. He is then placed in a slight Trendelenburg position and, to add to his comfort, a pillow is slipped under his head so as to raise it to the level of the pubis. In the male, a Drueck binder is applied in order to omit the scrotum

from the operative field. The anal and perianal skin are then painted with the following solution: picric acid, 5 per cent; acetone, 20 per cent; alcohol, 5 per cent; and water. The excess is dried with sterile gauze.

ANALGESIC SOLUTION

Procaine 1 per cent, or nupercaine 0.1 per cent (1:1000), or metycaine 1 per cent may be used, with the addition of adrenalin in the proportion of 2 to 3 drops to the ounce, to prolong the analgesic effect. The solution should be freshly prepared.

TECHNIQUE

Step 1 With a $\frac{3}{4}$ inch, 24 gauge hypodermic needle to which is attached a small syringe, an intradermal wheal is raised in the posterior midline, approximately three-quarters of an inch behind the anus. For this, only a few minims of the solution are necessary.

Step 2 A 3 inch, 22 gauge needle attached to a 5 cubic centimeter syringe is introduced through the wheal, and, with the index finger in the anal canal as a guide, the needle is slowly advanced parallel and posterior to the canal for a distance of approximately $1\frac{1}{2}$ inches. At this site, 10 cubic centimeters of the solution are deposited. If the patient feels discomfort, a few minims may be injected as the needle is advanced. The syringe is then detached and the needle is withdrawn up to, but not through, the wheal.

Step 3 With the finger in the rectum as a guide, this same needle is slowly inserted on the left side, deeply, forward, and outward, to the full extent of the needle, depending on the fullness of the buttocks. The syringe, charged with the analgesic solution, is now attached and 5 cubic centimeters are slowly injected into this area. Again the needle is withdrawn up to, but not through, the wheal.

Step 4 The needle is then inserted on the right side and the same procedure is followed as in Step 3. The posterior quadrant has now been completely injected, 5 cubic centimeters being used in the midline and 5 cubic centimeters on either side.

Step 5. With the technique described in Step 1, the second intradermal wheal is raised in the anterior midline, approximately a half inch in front of the anus.

calculi. Experiments on dogs suggest that damage may be done to the papilla of Vater by dilatation, with hemorrhage and inflammation in the acute stages. Later there is scarring resulting in a smaller opening than that which follows cholecystectomy alone. Clinically, perfusion pressures in patients during the postoperative period following exploration of the common bile duct with dilatation of the papilla show that there is a greater pressure when the papilla is extensively dilated than in those in whom it is not explored. We believe that it is sufficient to determine the patency of the papilla of Vater by the passage of moderate sized instruments instead of attempting to dilate it.

Fig 5 Nerves to the anorectal area showing their origin in the sacropudendal plexus

POSTOPERATIVE ANALGESIA

Prolonged analgesia may be obtained by the injection of 5 cubic centimeters of diothane, $\frac{1}{2}$ per cent solution, into the substance of the sphincter muscles (2, 3). In a series of approximately 450 cases treated by the author, freedom from severe pain was a constant feature in all but 11. Similar experiences have been reported (6, 9, 10).

PURPOSE

The anterior and posterior intradermal wheals serve to obtund the skin filaments and render subsequent injections painless. The posterior midline injection interrupts the posterior branch filaments of the inferior hemorrhoidal nerves, the anococcygeal nerves just below their perforation through the sacrotuberous ligament, and the perineal branch of the fourth sacral as it pierces the coccygeal muscle.

The posterolateral injections serve to analgesize the inferior hemorrhoidal nerves at a higher level, together with the perineal nerve and its posterior scrotal or labial branches, and the muscular branches of the dorsal nerve to the penis or clitoris.

The anterior midline injection inhibits the posterior scrotal nerves, its communicating fila-

Fig 6 Distribution and location of sensory nerves of the anal region

ments with the perineal branch of the posterior femoral cutaneous and its muscular branch to the superficial transverse perineal muscle.

The anterolateral injections obtund the terminal branches of the perineal nerve, the muscular branches of the dorsal nerve to the penis or clitoris, and the more anterior branch filaments of the inferior hemorrhoidal nerve.

CONCLUSION

In our hands this method has proved of utmost value and is to be highly recommended in all cases in which local analgesia is indicated. There is no pain, distortion, or bulging and complete muscular relaxation is obtained. The method is simple in the extreme, requiring only careful adherence to technique.

THE TREATMENT OF FISTULAS OF THE SMALL INTESTINE

JOHN B HARTZELL, M.D. F.A.C.S. Detroit Michigan

THE occurrence of a fistula of the small intestine in an abdominal wound is a distressing complication. The seriousness of such a fistula depends upon its situation in the intestinal tract. The higher the location the greater the menace it constitutes to the life of the patient.

A high small intestinal fistula may have a rapidly deleterious effect upon the general health. In certain cases practically everything taken by mouth is almost immediately expelled through the fistula with the result that speedy malnutrition occurs. More important than the loss of food is the enormous loss of fluid containing gastric and pancreatic juice, bile and intestinal secretion. This means a loss of the sodium and chloride ions so necessary in maintaining the fluid volume of the tissues. This results in prompt and severe dehydration and serious changes in the acid base balance of the blood plasma (14). There occurs a rise in the blood nitrogen and a drop in the blood chlorides so that early treatment is required or death soon follows. The loss of bile and intestinal secretion further depletes the body fluids but the continued loss of pancreatic juice has been shown to be fatal (13, 41). The situation as has been shown by Morton and Pearse closely resembles that found in instances of high intestinal obstruction when the loss of food fluid, and secretions is by vomiting instead of by way of a fistula.

In addition to the effect of a high small intestinal fistula upon the general condition of a patient there is a local effect of the intestinal content upon the tissues as it exudes through the wound. This material is rich in enzymes and di-

gests the tissues of the abdominal wall, often dissecting under the skin or fascia many inches to either side of the wound. As the secretions pour out upon the abdomen they also attack the skin causing widespread and painful excoriations. Secondary infection often results. The patient becomes rapidly toxic, and added to this physical suffering there is the additional burden of mental anguish as the patient realizes that some serious complication has occurred.

The treatment of small intestinal fistulas has been reviewed by Ochsner (27) and by McElyer. It is most important that the general condition of the patient be constantly watched. Active supportive measures should be started immediately. The fluid loss must be made up. This is best accomplished by the administration of large quantities of intravenous fluid. A 5 per cent glucose solution intravenously from 2 to 6 liters daily may be necessary to keep the blood nitrogen within normal limits. The blood chlorides should not be allowed to drop below 400 milligrams. This necessitates the daily administration of salt solution which is best given as normal saline intravenously or subcutaneously. If the patient is greatly dehydrated a fair amount may be absorbed by proctoclysis which should be given slowly as a Murphy drip. Blood transfusions may also be of benefit. With constant attention to these important features in the patient's care the problem of the treatment of the fistula itself must be dealt with.

If the fistula is small the use of the prone position on an anterior Bradford frame as suggested by Potter (33) may aid in preventing digestion of the skin. Many substances have been applied to the skin as a protection against this local irritation and among the more widely used are

various ointments and powders Zinc oxide is the most frequently used Lorch uses destin ointment combined with intensive irradiation Smith and Christensen use kaolin and glycerin The more extensively used powders are copper bronzing powder advocated by Cunningham Many substances have been used to inactivate or neutralize the irritating qualities of the discharge Egg albumen locally and by mouth has been used by Ochsner (28) Dried milk has been used by Rees and others Potter (32) applies one tenth normal hydrochloric acid to the skin, and inserts a tampon saturated with beef broth into the fistula Warshaw and Hoffman, Fox (12), and others report favorably upon the use of Potter's (32) method, some using peptone instead of beef broth

Patel and Carcassonne report the cure of one serious case by oral administration of fractional doses of 12 grams of calcium chloride per day. In addition, 10 units of insulin were given daily These authors do not discuss the theory of this treatment However, it is probably based upon supposed inhibitory effect of large doses of calcium upon motor and secretory activity of the gastro-intestinal tract (4) Dietary restrictions are of little benefit. Continuous aspiration of the secretion by means of a catheter has been successfully employed by Erdman, Cameron, Cheever, Lahey, Walters and Kilgore, Walters and Bollman, and Ochsner The use of two catheters, one in the efferent and one in the afferent loop so that the intestinal contents are redirected into the bowel, has been employed by Wilkie Volkman and Peet favor this method

The artificial closure of the fistula by various means has been tried by many authors The use of Beck's paste as described by Baker is an excellent method if the fistulous tract is over an inch in length and not of too great a diameter Judd and Phillips have used chewing gum Plugging the fistula with gauze soaked in oil has been advocated by Rigby, Hendon, Stadler, and Fechen Johnston describes a method of temporary closure of a fistulous opening consisting of a two way catheter, the openings of which are connected with two small balloons, one at the end and the second situated about 15 centimeters proximally The inner balloon is introduced into the lumen of the bowel and is then inflated with a small amount of air, an amount just sufficient to allow it to be pulled easily into the fistulous tract but not out of it The outer balloon is then inflated so that the whole balloon lies wholly upon the abdominal wall, thus holding the inner balloon firmly in place and sealing the fistulous opening

There is another method of dealing with a high small intestinal fistula which, though not always feasible, may often prove a life saving measure. This is the artificial closure of the opening by means of a button or small plaque inserted into the lumen of the gut and pulled back against the opening by means of a suture which is allowed to emerge through the fistula Though not always practical, this procedure is well worth a trial. Pamperl reports the case of Reybard, who over a hundred years ago advocated the closing of an abdominal wound which penetrated through the wall of the intestine by inserting a wooden button into the lumen of the gut The button was then pulled back snugly against the opening with a suture which passed out through the skin wound and was fastened to a crossbar lying on the surface of the abdomen Kleybolte, in 1842, described a similar device made of leather Another method of artificial closure is by the use of a T tube as first advocated by Kappis in 1911. He inserted the horizontal portion into the lumen of the bowel and allowed the vertical portion to protrude through the abdominal fistula Eliot has used this method. Kaehler and Pamperl have used a rubber tube split in half. Ahrens believes that the T tube is preferable as it tends to depress the mesenteric wall of the bowel where often there is a tendency to spur formation at the junction of the efferent and afferent loops Dowd in 1917 describes a small disc which he inserted into the lumen of the bowel and held against the opening with a suture which passed through a small obturator, or hollow axle-like shank of the right length and was tied to a second disc on the skin C. H. Mayo (24) in the same year used the Dowd button Cattell reports the successful use of this button in several cases C. W. Mayo (25) used a bakelite button in the closure of a gastrostomy opening The success of these various devices depends upon having a relatively small opening in the bowel with moderately firm tissue about the opening against which the button may be pulled. If the hole is large, involving one-half of the circumference of the bowel for instance, or if it is situated at an angulation, such a button will not stay in place. A T tube in this instance is also of little value. With a large opening the liquid bowel content leaks about the tube and the pressure of the tube against the friable inflamed bowel wall causes further necrosis

Surgical procedures at this time are fraught with serious dangers and with small chance of cure The bowel may be visible but the walls are usually so inflamed that any attempt to free the margins and close the opening by suture results

Fig. 1 Case 1 Condition of the abdominal wound at the time the rubber disc was first inserted. The opening in the bowel is visible in the lower angle of the wound. The rubber disc is shown in the outline held in place within the lumen of the bowel by a suture which emerges through the opening and is tied to a crossbar on the surface of the abdomen. There is a marked excoriation of the skin. The two counter incisions are shown one below the right costal border and one in the right groin. The intestinal drainage had dissected under the skin to these areas and abscesses had formed.

Fig. 2 The rubber disc which was used in Case 1

in the tearing of the bowel and increasing the size of the fistula. If the abdomen is opened with the idea of excising the fistula and doing an anastomosis or an enterostomy, there is the serious possibility of contamination with resulting peritonitis. Many operative procedures have been suggested, but any radical surgery is obviously contra indicated except when there is an obstruction lower down in the efferent segment. Rokhkind lists a second exception, namely when the defect in the intestinal wall is so large that the entire content is lost externally.

If there is any possibility of an obstruction in the efferent loop its presence should be determined at the earliest possible moment. Such an obstruction may be responsible for the appearance of a fistula in the first place. The wall of the exposed loop of bowel in an open infected wound is

much more likely to give way if there is an obstruction distal to it than if the bowel lumen is patent. Therefore if an obstruction is suspected it is well to insert a catheter through the fistula and into the efferent loop and inject an ounce or two of mineral oil. This will appear rectally if there is no obstruction. If the oil does not appear immediate operation for the relief of the obstruction is imperative as any attempt at closure of the fistula either by artificial or surgical means is futile. It may be possible to locate the exact site of the obstruction by injecting a small amount of barium into the efferent loop and following its course with the x ray. The longer the delay the greater the certainty of a fatal outcome. However if it could be determined that the obstructed area was situated well away from the fistula, it might prove more practical to make the incision directly over the obstructed area do an entero-anastomosis about it and rely on artificial closure of the fistula. Then as the general condition of the patient improved this could be closed later if it did not close itself.

So much for the necessity of immediate surgical interference. Now to consider the small intestinal fistula with an opening so large that the entire

Fig 3 The rubber disc has been rolled up and it is being inserted into the lumen of the bowel.

Fig 4 A sagittal section showing rubber disc inside the lumen of the bowel and pulled against opening by a suture which passes out through the fistula

content of the afferent loop is lost externally. We have devised a refinement of the button and tube method of artificial closure which may work where these may not. Let us consider such a fistula situated at a knuckle and involving about half the circumference of the bowel with a gaping and infected wound from which the intestinal contents flow in an almost uninterrupted stream. First we introduce a probe into the bowel to determine the approximate size of the lumen and the angle at which the afferent and the efferent loops meet at the opening. We then mold a wax model of the proper size and proper angle and with sufficient belly to receive the intestinal content from the efferent loop and shunt it around the corner into the afferent loop. This mold must be long enough to extend well beyond the area of the necrotic bowel. The general shape may be that of a half tube or an angulated tube from which a longitudinal strip, the width of a quarter to a half of the circumference, has been cut away. This wax model is then cast in pliable rubber which is easily folded up and inserted into the bowel but is stiff enough to return to and maintain its original shape. Into the exposed portion we place a heavy silk suture which is allowed to emerge through the fistula and is fastened to a crossbar on the surface of the abdomen. If the rubber cast does not stay in place, two sutures, one through either end and brought out through the bowel wall and abdominal wall will hold it there. The wound is then approximated with one or two large sutures or possibly a strip of adhesive tape. The leakage stops, the intestinal content is diverted into the bowel below the fistula. The general condition of the patient improves. The wound rapidly loses its angry appearance. With a little ointment on the skin and irrigation of the

wound, granulations soon appear and bridge across. After a short time the condition of the tissues may be so improved as to warrant surgical closure of the opening. Or if the opening is closing and becoming smaller, this cast may be withdrawn and replaced with a smaller one. When the granulations grow snugly about the thread, the latter may be cut, the button passes, and the fistula soon seals itself and heals completely. We feel this to be an improvement in the treatment of high intestinal fistulas as compared to early and more radical procedures.

SUMMARY

The treatment of small intestinal fistulas has been reviewed.

The presence of an obstruction distal to the site of a fistula constitutes the one all important reason for immediate surgical interference.

The practicability of closure of a small intestinal fistula by artificial means is stressed.

In the presence of a large fistulous opening, where other types of artificial (button) closure are unsatisfactory, the use of the rubber cast as described here, may prove a life saving measure.

Four cases are reported.

CASE 1 A male, 39 years old, was operated upon for sub-acute appendicitis. The operation was easily performed through a right rectus incision. An intestinal obstruction occurred. The patient was again operated upon on the fifth postoperative day. The obstruction was found to be due to an old fibrous band which constricted the small bowel at the level of the lower jejunum. This band was cut and the bowel freed. Just proximal to the band was a necrotic area which perforated spontaneously. The margins of this opening could not be approximated. An entero-anastomosis was made between this portion of the bowel and an empty loop distal to it. The anastomosis worked very well. Four other smaller perforations occurred in the distended necrotic bowel above the anastomosis. It was possible to close

Fig 5 Case 2 Condition of the abdominal wound at the time the rubber cast was first inserted. A knuckle of bowel is visible in the base of the wound. The top of this knuckle has sloughed off leaving a large hole. There is marked excoriation of the skin. The rubber cast is shown in place within the lumen of the bowel, held in place by a suture through either end which passes out through the bowel wall and the abdominal wall. There is a third suture fastened to the cast at the knuckle. This emerges through the fistula. This suture was later tied to a crossbar on the surface of the abdomen.

Fig 6 Sagittal section showing the rubber cast inside the lumen of the bowel. The sutures through either end of the cast pass out through the bowel wall and abdominal wall, and are tied on the skin. The central suture emerges through the fistula and is tied to a crossbar on the surface of the abdomen.

Fig 14 Case 3 Appearance of the abdominal wound 3 weeks after operation.

all these except one. The tissue about this was so friable that it was impossible to approximate the margins. A soft catheter was inserted through this hole into the lumen of the bowel, and brought out through the omentum which was tucked over this whole portion of discolored inflamed bowel. This catheter was brought out through the wound as an enterostomy. The enterostomy tube worked well. The wound became infected with colon bacilli which neces-

sitated the removal of several stitches, and on the sixth day a fecal fistula occurred. The opening in the bowel could be seen in the lower angle of the incision (Fig 17). Food and fluids came through this opening within 5 minutes after being taken by mouth. The wound infection progressed. There was a copious amount of intestinal drainage pouring from this opening in a nearly constant stream. This material was very irritating. It excoriated the skin and dissected

under it to either side of the wound. A tender mass appeared below the right costal border and a second in the right inguinal region. These were incised and drained. They proved to be abscesses and were connected with the wound.

The patient lost ground rapidly. The blood nitrogen mounted. The enterostomy tube stopped draining and was removed. Many different ways of dressing the wound were tried but the drainage was so copious that the surface of the abdomen was almost constantly flooded with this irritating intestinal content. Finally a soft rubber button was devised out of two layers of rubber tissue (Fig 2). This disc or button was then rolled up and inserted into the lumen of the gut (Fig 3) and pulled back against the opening in the bowel (Fig 4) by means of a suture which was allowed to emerge through the incision and was fastened to a cross bar on the surface of the abdomen (Fig 5). The

drainage of intestinal content stopped immediately. The patient's general condition rapidly improved. The wound infection cleared up. Healthy granulation tissue soon grew firmly about the thread. Six weeks after the insertion of this rubber disc the suture was cut and the button passed. The fistula had sealed itself. One week later the patient was without a dressing.

CASE 2 A male 42 years of age was operated upon by a colleague for chronic appendicitis and to free abdominal adhesions. On the tenth day a wound infection developed. The wound was probed—gas and fecal matter escaped. He was first seen in consultation 2 weeks after the operation. The fistula had been discharging for 4 days. There was a large gaping infected wound with marked excoriation of the skin. The opening in the bowel which was visible was large and situated at an angulation. All foods and fluids taken by mouth were soon lost through the fistula. The ordinary

type of button would not stay in place. A rubber cast was made from a wax model as previously described (Fig. 7) and inserted into the bowel (Fig. 9). A suture was first placed through the angle or knuckle of the rubber cast to hold it. This was at first anchored to the skin with a tab of adhesive tape (Fig. 8). It was later tied to a crossbar in order to pull the cast more snugly against the opening in the bowel. Two more sutures were then placed in the cast, one through either end (Fig. 7). These were brought out through the bowel wall and abdominal wall (Figs. 5 and 6) and tied in place (Fig. 8). The wound was loosely approximated. There was only a slight amount of leakage thereafter. The general condition of the patient improved. The condition of the wound improved so much that a simple secondary closure was performed 2 weeks later. This was successful and the patient was able to leave the hospital on the fifteenth day.

CASE 3. A male, 17 years of age, was shot through the body with a No. 22 rifle. The bullet entered just to the left of the twelfth thoracic vertebra, passed through the pleural cavity, perforating the lower lobe of the lung, diaphragm, liver and stomach, and emerged through the fifth interspace in the left nipple line. An abdominal exploration was performed a few hours later and the stomach perforations were sutured. The postoperative course was stormy, with fever, 102 degrees and distention of the abdomen. On the eighth day the patient suffered a severe hemorrhage from the stomach necessitating a transfusion. On the tenth postoperative day the wound opened up and was resutured. Five days later a fecal fistula appeared, and patient was put on a Bradford frame. At the end of the third week he developed an empyema of the left thoracic cavity. Closed drainage was instituted. In the fourth week an appendiceal abscess was discovered and drained. All this while the fistula was draining copiously. I first saw the patient in consultation with regard to the fistula, approximately 1 month after his accident. At that time he had a large fecal fistula in an upper abdominal wound. His weight had dropped from 108 pounds to approximately 50 or 60 pounds, and he was in a truly pitiful condition. Ointments, powders, suction, in fact a long list of things had been tried with little or no success. The mucous membrane had grown to the skin as in a permanent colostomy (Fig. 10). The opening was about the size of a half dollar. A rubber cast was made and inserted. From that day the general condition of the patient gradually improved. During the course of the next month 3 operations were performed. The right lower quadrant was explored, a rib resection was done, and open drainage of the empyema was instituted. Also, a left subdiaphragmatic abscess was drained. Four months after the accident the patient was able to leave the hospital. By this time he had worn the button for 3 months and was looking after it himself. Sometime later he made one for himself out of an inner tube. He wore this button until June, 1937. He was able to ride a bicycle and play golf. His general condition improved so much that early in June the incision was opened. The fistulous opening was excised together with about 3 inches of bowel proximal and distal to the opening. An end-to-end anastomosis was performed and the patient was able to leave the hospital with a healed wound in about 2 weeks. This case affords an excellent example of the value of this rubber button type of closure. It was worn continuously for over 8 months, during which time the patient underwent three serious major operations. He recovered and gained in general strength sufficiently so that he was able to go home and lead a fairly normal and comfortable existence until his general health had improved to such an extent as to permit him to withstand a resection of his bowel.

CASE 4. A colored female, aged 29 years, was admitted to the hospital with a strangulated umbilical hernia, with a two day history of abdominal pain, emesis, and fever. The white blood count was 14,700, and the polymorphonuclear count was 92 per cent. An operation was performed within a few hours. A small incision was made over the mass just above the umbilicus. A small loop of jejunum was found incarcerated in a sac. It appeared black but was thought to be viable. It was dropped back and the hernia repaired. The postoperative course was stormy—fever, 101 to 103.6 degrees, pulse, 100 to 140, marked abdominal distention partially relieved by Wangenstein suction. A bronchopneumonia and pleurisy developed. The general condition improved slightly. On the tenth postoperative day the pulse was still elevated, and the abdomen still distended. On the twelfth postoperative day, a fecal fistula appeared in the wound. This drained more copious amounts each day. The patient was given 3000 to 4000 cubic centimeters of intravenous glucose and saline daily. However, 1 week later, in spite of this intensive treatment, the blood urea was 121.7 milligrams per cent and the blood chloride was 346.5 milligrams per cent. She was seen in consultation on this same day. The wound was open, the fistula visible in the base of the wound. It was impossible to keep the wound dry, and there was much necrotic tissue along the margins of the wound. Several times in the course of inspection of the wound, 100 to 200 cubic centimeters of intestinal content gushed out, flooded the abdomen, and ran into the bed. The fistula was about 1 centimeter in diameter. It was explored with the finger and found to arise from a slightly constricted portion of the bowel. The bowel for a distance of about 2 centimeters to either side of the fistula felt firm and indurated. Beyond that it seemed to be normal. A soft rubber button was made similar to the one devised for Case 1. It was rolled up and inserted into the lumen of the bowel, and pulled back by means of the attached thread which was fastened to the skin. The patient's condition remained about the same for 2 days. The temperature and pulse remained elevated, temperature, 101 to 104 degrees, pulse, 110 to 120. A continuous intravenous infusion was started, and within 2 days she appeared much improved. The temperature and pulse levelled off to normal, and in 3 days the blood urea had dropped from 121.7 milligrams per cent to 49.2 milligrams per cent, and the chlorides had risen from 346.5 milligrams per cent to 412.5 milligrams per cent. The wound rapidly cleared up. The button came out two or three times in the first 48 hours. After that it remained in place, and there was no leakage. The wound margins were approximated with adhesive tape and a cod liver oil and vaseline dressing was applied. Three weeks from the time the button was introduced, the wound was healed except for a small sinus through which the thread passed out and was fastened to the skin of the abdomen. The patient was up and about. At this point the thread was cut, the button passed, and the patient was completely healed within a week.

UTERUS BICORNIS DUPLEX ASSOCIATED WITH INFECTION DUE TO MICRO-AEROPHILIC HEMOLYTIC STREPTOCOCCUS

EDWARD B. SELF, M.D., and FRANK L. MELENEY, M.D., F.A.C.S., New York, New York

CONGENITAL malformations of the uterus have been classified in various ways by different authors. The following grouping, suggested by Strassmann, appears to be the most satisfactory:

1. Uterus septus—the septum extends through the body of the uterus and the cervix. It may or may not pass down to divide the vagina in half.

2. Uterus subseptus—the septum is incomplete.

3. Uterus bicornis—a uterine horn is free on both sides. Depending upon the degree of separation and non-union of the horns there result here the following subgroups:

a. Uterus arcuatus—there is simply a slight indentation or notch in the fundus, resulting in a heart-shaped uterus.

b. Uterus bicornis unicollis—the indentation further separates the two horns, they being joined at a point only a short distance above a single cervix.

c. Uterus bicornis duplex—the horns are further separated, but the adjacent walls are fused just above the cervical level. There are two distinct cervixes and there may or may not be two vaginas.

d. Uterus didelphys—there is complete separation of the horns with formation of a true double uterus. There are two cervixes and two vaginas. This anomaly is the rarest of all.

No attempt will be made here to discuss the embryology of the uterus in detail. Suffice it to say that most uterine malformations are the result of improper fusion of the two müllerian ducts, resulting in an accentuation of what are called horns in the adult uterus. Many theories have been advanced to explain the factors responsible for this failure of fusion of the ducts, and among them the following seem most worthy of mention. In the case of many of the theories, the proponents have failed to advance tangible evidence in support of their ideas.

1. Prominence of a rectovesical ligament. This ligament is frequently found between the two

horns of a normal single uterus, and between those of a bicornate uterus. However, this ligament might just as well be a part of the anomalous condition itself as its cause.

2. Fetal peritonitis, the resulting adhesions preventing fusion of the ducts. This course of events must be exceedingly rare, if indeed it occurs at all.

3. Abnormal persistence of a cloaca, or

4. Disturbance of development of the intestinal tract or bladder, the abnormalities thus preventing normal union of the two ducts.

5. Too short round ligaments, or

6. A broadening (widening) of the bony pelvis, again preventing proper fusion.

7. Variations in the germ plasma itself.

It is probable that one or more of these factors play a part, varying in different instances.

Congenital malformations of the uterus are not rare, but relatively few cases are recognized during life. Statistics as to their frequency are confusing because the exact nature of the anomaly is not always accurately described by the author, and there is often disagreement as to which name should be applied to the particular anomaly in question. Various statements occur in the literature concerning the frequency of the rarest anomaly, i.e. uterus didelphys. Findley quotes Stolper as having found 10 cases in 7,400 married women, and Neugebauer as finding 3 cases in 19,000 examinations, but whether the observations were made clinically or postmortem is not stated. Findley himself was able to collect from the literature 135 true cases of uterus didelphys up to 1926. With regard to the more common bicornate uteri, Falls says "the frequency is estimated to be 1 per cent," but gives no statistical proof of his statement.

As a rule doubling of the uterus does not assume clinical significance until the advent of pregnancy, and even at such a time the condition is frequently unrecognized. Many amusing reports occur in the literature concerning the confusion which has resulted from failure to recognize the abnormality. In breech presentations, when the septum is incomplete, one leg may pass down one side, the other leg down the other side, and the

always been irregular, occurring every 14 to 21 days, always accompanied by severe dysmenorrhea; flow variable.

Patient was entirely well until 2½ years ago at which time she was suddenly seized with a sharp pain running from the lower lumbar spine to the right hip. This pain remained constant, did not radiate in any particular direction, was not associated with nausea, vomiting, change of bowel habits, genito-urinary or gynecological symptoms. The pain was at first severe enough to keep her home from work and to prevent sleep. There was no preceding history of trauma. After 3 days of treatment with hot water bags, the pain disappeared. After that she had similar attacks of pain, occurring several times a year, but between the attacks she remained quite well. A severe attack 9 months before admission was diagnosed as acute appendicitis. Operation was advised but refused and the pain gradually subsided. Fifteen weeks before admission the patient was seized with a similar attack of pain. The surgeon advised immediate operation, which was performed in the hospital in North Adams, Massachusetts. An abscess was found in the right lower quadrant of the abdomen and right side of the pelvis. The surrounding tissues were acutely inflamed and glued together with fibrinous exudate. The surgeon was not sure whether the appendix or the right tube was the primary focus of infection, and he decided to drain the abscess. A culture of the pus was reported to yield a hemolytic streptococcus. The wound continued to drain and the fever was maintained. Five weeks later the wound was reopened and another large abscess was found and drained. But this abscess likewise continued to drain profusely, and the patient suffered much pain. Her fever continued, her appetite failed, she lost weight and strength, and developed pressure sores on her back. Finally the region of the right hip became swollen and the right thigh tender and painful. She was seen in consultation by one of us (F.L.M.) in the North Adams Hospital. It was obvious that the infection had spread extensively and required further drainage. The doctors in charge of the case advised transferring the patient to New York for the purpose of further treatment. Although it was recognized that the risk of transportation was great, it seemed best to make the change. The trip of 180 miles was very tiring.

On arrival the patient was pale and emaciated and evidently in considerable pain and discomfort. The temperature was 101.6 degrees and the pulse was rapid. The eyes, ears, and nose were essentially negative. The mouth was dry; the tongue coated, the throat was normal. No enlarged glands were felt in the neck. The lungs were clear. The muscular tone of the heart was feeble, and there was a systolic murmur over the pulmonic area. The abdomen was moderately distended and everywhere tender. In the lower abdomen to the right of the midline was an ulcerated area with undermined margins. In the depths of the ulcer, a sinus led through the abdominal wall down toward the right lower quadrant. From it large quantities of pus were discharging (Fig 1). The right lower quadrant above Poupart's ligament was bulging and there was a large area of fluctuation just beneath the skin. The upper third of the right thigh was swollen and edematous with fluctuation over Scarpa's triangle. Pressure here caused pus to pour forth from the abdominal sinus. The posterior surface of the thigh also revealed deep fluctuation. The hip joint, however, could be moved without great pain. The right leg as well as the whole left lower extremity showed considerable wasting.

The patient was obviously too sick to stand an immediate operative procedure. She was given fluids and a sedative. The white blood count was 11,700, with 65 per cent polymorphonuclear leucocytes. The urinalysis was negative. On the day after admission the patient seemed

Fig 3 Extent of abscesses as seen at operation

a little better and stereoscopic films of the pelvis and right thigh were made before and after the injection of lipiodal into the abdominal sinus. The report follows: "The oil puddled along the psoas margins retroperitoneally, and the tip of the catheter extended as far as the first lumbar level. There is an obvious cavity with gas in it, lying in the anterior thigh region, and it is reasonable to suppose that the two cavities communicate. There is no evidence of bone pathology. The hip joint is not unusual" (Fig 2).

On the third day the patient was very uncomfortable and cried whenever she was touched or moved, but her general condition was slightly improved. It seemed best not to delay the operation. Long incisions were made on the anterior and posterior aspects of the thigh and large quantities of pus were released from a cavity surrounding the upper third of the femur. This cavity extended upward along the iliopsoas muscle into the retroperitoneal space where a large mass of necrotic tissue lay in a huge abscess cavity. This abscess was drained through an oblique incision above Poupart's ligament (Fig 3). The whole infected area was flooded with a suspension of zinc peroxide in distilled water. The wounds were lightly packed with gauze soaked in this suspension and the dressing was sealed with vaseline gauze.

Culture of the pus obtained at operation showed a microaerophilic hemolytic streptococcus, an anaerobic non-

Fig 1 Appearance of ulcer of abdominal wall upon admission

baby thus straddles the septum. Cases of superfetation are reported (22), one woman giving birth to a 7 months' infant followed 3 days later by a fetus approximately 3 months in age. Confusion in diagnosis has resulted from the fact that one condition may be noted by the first observer on one side of the vaginal septum, while a consultant, who examines the other cervix, is unable to corroborate his colleague's impression. Diagnoses have been made of ovarian cysts, myomas, or even ectopic pregnancies. Women with double uteri conceive readily 40 per cent, however have complicated deliveries (21) and abortion and premature labor occur frequently, 17 per cent develop retention complications. There is unusual fertility in some cases. In one instance (21) there were delivered 1 baby in the first pregnancy, 2 in the second, 3 in the third, 4 in the fourth and 3 in the fifth, making a total of thirteen babies in five pregnancies! In the last labor the uterus ruptured.

Of the lesions associated with double uterus hematometra is the most frequent. When it occurs on one side only, menstruation by the other uterus will confuse the diagnosis. As would be expected dysmenorrhea is a common symptom.

Other lesions which have occurred in association with double uterus are tumors of one cornua (polyps 2, fibroma 6, adenomyoma carcinoma 24, chorionepithelioma 8, hematocolpos salpingitis, 4, ovarian cysts tumor in an hemiatretic horn 32, ovarian abscess 4, inguinal hernia containing a horn of a bicornate uterus, 25, acute intestinal obstruction due to pregnancy in a bicornate uterus, 25, empyema of cervical cyst 12).

Fig 2 Roentgenogram showing gas filled abscess cavity in thigh

Several patients were operated upon with a diagnosis of acute appendicitis (17, 26).

Findley emphasizes the fact that absence of the right kidney and ureter is a frequent associated anomaly in this condition, and he suggests preliminary catheterization of the ureters before any operative procedures are done. In one instance in which hysterectomy was done, the only existing ureter was severed. In the case to be presented herewith one kidney was absent.

We have been able to find records of comparatively few cases however in which infection played a prominent part in the clinical picture. Several of these were gonococcal in origin (8), while 2 developed a streptococcus peritonitis (9, 29). In the case reported by Mihailenco a condition was found (pyocolpos and pyometros with retroperitoneal extension) which was very similar to the case to be presented.

The following case is reported as an interesting example of an uncommon uterine anomaly associated with infection due to a microaerophilic hemolytic streptococcus.

B. S. female age 24 years, Massachusetts textile mill worker, was admitted to Presbyterian Hospital, New York City, February 22, 1937. Unit history No. 511348. The family history was irrelevant. Patient had been married 8 years and had not been pregnant. Husband was living and well. Occupation—cotton spindle operator. She had had no previous illnesses or operations. Menstrual periods had

always been irregular, occurring every 14 to 21 days, always accompanied by severe dysmenorrhea; flow variable

Patient was entirely well until 2½ years ago at which time she was suddenly seized with a sharp pain running from the lower lumbar spine to the right hip. This pain remained constant, did not radiate in any particular direction, was not associated with nausea, vomiting, change of bowel habits, genito-urinary or gynecological symptoms. The pain was at first severe enough to keep her home from work and to prevent sleep. There was no preceding history of trauma. After 3 days of treatment with hot water bags, the pain disappeared. After that she had similar attacks of pain, occurring several times a year, but between the attacks she remained quite well. A severe attack 9 months before admission was diagnosed as acute appendicitis. Operation was advised but refused and the pain gradually subsided. Fifteen weeks before admission the patient was seized with a similar attack of pain. The surgeon advised immediate operation, which was performed in the hospital in North Adams, Massachusetts. An abscess was found in the right lower quadrant of the abdomen and right side of the pelvis. The surrounding tissues were acutely inflamed and glued together with fibrinous exudate. The surgeon was not sure whether the appendix or the right tube was the primary focus of infection, and he decided to drain the abscess. A culture of the pus was reported to yield a hemolytic streptococcus. The wound continued to drain and the fever was maintained. Five weeks later the wound was reopened and another large abscess was found and drained. But this abscess likewise continued to drain profusely, and the patient suffered much pain. Her fever continued, her appetite failed, she lost weight and strength, and developed pressure sores on her back. Finally the region of the right hip became swollen and the right thigh tender and painful. She was seen in consultation by one of us (F.L.M.) in the North Adams Hospital. It was obvious that the infection had spread extensively and required further drainage. The doctors in charge of the case advised transferring the patient to New York for the purpose of further treatment. Although it was recognized that the risk of transportation was great, it seemed best to make the change. The trip of 180 miles was very tiring.

On arrival the patient was pale and emaciated and evidently in considerable pain and discomfort. The temperature was 101.6 degrees and the pulse was rapid. The eyes, ears, and nose were essentially negative. The mouth was dry, the tongue coated, the throat was normal. No enlarged glands were felt in the neck. The lungs were clear. The muscular tone of the heart was feeble, and there was a systolic murmur over the pulmonic area. The abdomen was moderately distended and everywhere tender. In the lower abdomen to the right of the midline was an ulcerated area with undermined margins. In the depths of the ulcer, a sinus led through the abdominal wall down toward the right lower quadrant. From it large quantities of pus were discharging (Fig. 1). The right lower quadrant above Poupart's ligament was bulging and there was a large area of fluctuation just beneath the skin. The upper third of the right thigh was swollen and edematous with fluctuation over Scarpa's triangle. Pressure here caused pus to pour forth from the abdominal sinus. The posterior surface of the thigh also revealed deep fluctuation. The hip joint, however, could be moved without great pain. The right leg as well as the whole left lower extremity showed considerable wasting.

The patient was obviously too sick to stand an immediate operative procedure. She was given fluids and a sedative. The white blood count was 11,700, with 65 per cent polymorphonuclear leucocytes. The urinalysis was negative. On the day after admission the patient seemed

Fig. 3 Extent of abscesses as seen at operation

a little better and stereoscopic films of the pelvis and right thigh were made before and after the injection of lipiodol into the abdominal sinus. The report follows: "The oil puddled along the psoas margins retroperitoneally, and the tip of the catheter extended as far as the first lumbar level. There is an obvious cavity with gas in it, lying in the anterior thigh region, and it is reasonable to suppose that the two cavities communicate. There is no evidence of bone pathology. The hip joint is not unusual" (Fig. 2).

On the third day the patient was very uncomfortable and cried whenever she was touched or moved, but her general condition was slightly improved. It seemed best not to delay the operation. Long incisions were made on the anterior and posterior aspects of the thigh and large quantities of pus were released from a cavity surrounding the upper third of the femur. This cavity extended upward along the iliopsoas muscle into the retroperitoneal space where a large mass of necrotic tissue lay in a huge abscess cavity. This abscess was drained through an oblique incision above Poupart's ligament (Fig. 3). The whole infected area was flooded with a suspension of zinc peroxide in distilled water. The wounds were lightly packed with gauze soaked in this suspension and the dressing was sealed with vaseline gauze.

Culture of the pus obtained at operation showed a microaerophilic hemolytic streptococcus, an anaerobic non-

Fig. 4 Uterus bicornis duplex

hemolytic streptococcus, an aerobic green streptococcus, a hemolytic and a non hemolytic colon bacillus, and an anaerobic gram negative bacillus *Bacillus fusiformis* necrophorus. The patient's condition was poor following operation. The blood pressure fell to 80/40, but after an infusion rose to 110/58. The white blood count fell to 6,500. On the morning of the day after operation the temperature fell and the patient seemed better although the pulse remained rapid. On the second postoperative day the patient went into shock and became comatose, the blood pressure falling to 60/40. An attempt was made to restore her with infusions with cortin and with transfusion but the pulse gradually failed and she expired.

The necropsy (No. 12390) was performed 2 1/2 hours postmortem. The body was undernourished and poorly developed. There was a scar 12 centimeters long in the lower midline of the abdomen, its distal 8 centimeters gaping open to form an oval cavity 5 centimeters in width and 2 centimeters in depth. This cavity was lined with purplish red granulation tissue on which lay a fibrous exudate and gray coarsely granular powder (zinc peroxide) 1 cm from the base of the cavity a sinus tract 1.5 centimeters in diameter extended inward. Recent large gaping incisions were present on the anterior and posterior aspects of the right thigh and another in the right lower quadrant of the abdomen parallel to Poupart's ligament and to the right iliac crest. These wounds extended deeply and were continuous with large cavities that completely surrounded the upper right femur and passed upward over the iliopsoas muscle to communicate with the retroperitoneal abscess cavity (Fig. 3). The walls of the cavities were lined with infected granulation tissue.

The peritoneal cavity contained 1200 cubic centimeters of turbid grayish yellow fluid in which were suspended flecks of fibrin. The peritoneum was everywhere injected and fibrous exudate bound together loops of intestine. The inflammatory reaction appeared to be recent.

The other abnormal findings were limited to the genito-urinary system. The right kidney and ureter were absent. The left kidney was large, weighing 340 grams and measuring 15 by 7 by 4.5 centimeters. It was grossly and histologically normal. The bladder was normal except for the absence of the right ureteral orifice. Inflammation of the serosa was the only abnormality of the alimentary tract.

The uterus was large, measuring 8.5 centimeters in length, 6.4 centimeters in width, 2.5 centimeters in thickness. It was bicornate and its general appearance and relationships are shown in Figure 4. The cervix of the left uterus was normal except for the fact that its canal was 5 centimeters in length. There was no cervix on the right, the right uterine cavity terminating in a pear-shaped pouch 3.5 centimeters in its longest dimension. The inner surface of the pouch was smooth and glistening, its wall was found to be composed of dense fibrous tissue and smooth muscle covered by granulation tissue. In places were patches of endometrial tissue containing glands. The two uterine cavities communicated with each other by means of a passage 1 millimeter in diameter through the septum about 1 centimeter above the cervix. The cavities of the right uterus and of the blind vaginal pouch were filled with thick green pus, and a few drops of pus also were present in the left uterus where it had extended via the communicating passageway. The tissues about the right uterus were undurated and in two places small cavities budded off the right uterine cavity where extension of the infection had occurred. There was a pyosalpinx on the right and the right ovary was represented by several multiloculated cystic spaces, some of which contained pus. Communication between this infected ovary and the retroperitoneal abscess was demonstrated. There was a hydrosalpinx on the left and the left tube and ovary were abnormally located, the tube lying mainly behind the fundus, the ovary against the body of the uterus.

The appendix showed no evidence of having been the primary focus of the infection. Fibrous adhesions pulled its tip down into the pelvis so that it lay lateral to the end of the right fallopian tube.

The left uterus was lined with normal endometrium while the endometrium of the right one was atypical, there being fewer glands present and in places areas of stratified squamous epithelium. The right fallopian tube presented a picture of subacute inflammation.

A culture of the pus obtained at the first operation at the North Adams Hospital yielded a hemolytic streptococcus. It is not certain whether this organism was obtained on direct plating of the pus or whether it appeared more slowly on liquid media. However, with the history of prolonged drainage of a pelvic abscess yielding on culture a micro-aerophilic hemolytic streptococcus along with other intestinal organisms, it is reasonable to suppose that the hemolytic streptococci were the same. Either the organism was micro-aerophilic at the start or in the course of the prolonged infection it took on anaerobic properties.

Infections caused by the micro-aerophilic hemolytic streptococcus are characterized by prolonged suppuration with extensive burrowing. Although they are usually associated with infections of the skin and subcutaneous tissues producing chronic undermining ulcers, they also tend to burrow into the deeper tissues. In this case there was an undermining ulcer of the abdominal wall but the principal lesion resulted from the burrowing of the infection upward along the psoas muscle to the lumbar region and downward into the thigh. The

formation of gas in the tissues indicated the activity of one or more of the contaminating organisms, either the anaerobic non-hemolytic streptococcus, the colon bacillus, or the *Bacillus fusiformis necrophorus*. Infection also terminally spread into the peritoneal cavity proper. It is not certain whether that spread occurred at the time of the operation and as a result of it, or a short while before. No communication was found between the abscess cavity and the peritoneum but a tiny opening might have been made in spite of the great care that was taken to avoid it at the time of the operation. In a similar case reported elsewhere (18) death occurred from peritonitis when the peritoneum was opened in an attempt to eradicate the infection by excision.

It is important to consider how this organism entered the patient. It may have come through the blood stream, perhaps gaining entrance from the throat, or from the intestine by direct extension from adherent loops of gut, or from the appendix. A more likely portal of entry was the anomalous uterus, for the following reasons:

1. The organism is occasionally found in the normal vagina
2. Of 16 cases of infection with micro-aerophilic hemolytic streptococcus reported previously by one of us (F.L.M., 18, 19), 7 were pelvic infections in women, in whom the uterus and tubes were the probable portals of entry. The organism thus appears to have a predilection for the uterus and tubes
3. Assuming that the organism gained entrance through the vagina, it must have entered the left uterus and either have passed through the opening in the septum to the right side or have passed through the left tube into the pelvis and thence to the right side. The infection may have become established in the right "vaginal pouch" with subsequent spread to the right uterus, tube, and ovary, or it may have started first in the tube, with later extension to the ovary and uterus. The microscopic study showed the inflammatory changes in the tube to be of longer duration and greater severity than those in the uterus. It is likely that a long standing hematometra or hematocolpos served as a *locus minoris resistentiae* that favored the establishment of the infection.

It is probable that the infection could never have been eradicated in this case because of the nature of the congenital anomaly. Any attempt at removal of the infected uterus and tube from above would almost certainly have caused a fatal peritonitis. Drainage from below would have been ineffective. In either event it would have been impossible to obtain contact between the zinc peroxide and the deepest foci of the infection in the uterus and tube. It is possible that sulphanilamide might have had a beneficial effect on the hemolytic streptococcus if it had been used in the early stages of the disease, but it would have had no effect during the later stages when other organisms were present.

IMMEDIATE VERSUS DELAYED SURGERY IN ACUTE CHOLECYSTITIS

THE surgical management of acute cholecystitis has long been a subject of discussion because of differing opinions regarding the advantages of immediate rather than delayed surgery in this condition. Years ago, surgical opinion was preponderantly in favor of delay in operating for acute cholecystitis until the active inflammatory process had subsided. In recent years, however, this viewpoint is definitely changing as shown in papers by Miller, Stone and Owings, Andrews, Heuer, and others, and an increasing number of surgeons are finding immediate cholecystectomy the treatment of choice in acute cholecystitis. Further evidence of the changing modern viewpoint was recently given in the editorial by Heyd in this *Journal*. Immediate operation in acute cholecystitis is the treatment of choice in my opinion, not only because clinical experiences with it have been good but also because it is

my belief that the pathological condition present makes early operation positively indicated.

Most students of the pathology of acute cholecystitis now agree that obstruction to the cystic duct is the primary lesion in this disease, and that infection, when it occurs in these cases, is a secondary phenomenon which is dependent on this obstruction for its development. Usually a stone causes the obstruction to the cystic duct. Following this obstruction, comes swelling of the gall bladder with resultant pressure on the veins and lymphatics that lie in close relation to the tortuous folds of the cystic duct. In some cases, branches of the cystic artery are occluded and infarction of parts of the gall bladder wall appear. Gangrene and even perforation may occur if the edema, infarction, and necrosis advance. The time necessary for these changes to appear after a stone is impacted in the cystic duct will vary with the completeness of the obstruction to the duct and with the anatomical arrangement of the blood vessels in the individual case.

Studies of the bacteriology of acute cholecystitis by Wilkie, Denton, Feinblatt, Andrews, and others have all shown that infection of the gall bladder is *not* the primary etiological factor in acute cholecystitis. Most workers agree with Feinblatt and with Denton that the rôle of infection as a cause of cholecystitis has been greatly overestimated. The recent studies by Andrews show that bacterial infection plays a very minor rôle in this disease. All recent students of the bacteriology of acute cholecystitis agree that metabolic, mechanical or circulatory changes must be present in the gall bladder before bacterial infection will occur.

Clinically, these findings are confirmed by the course of many cases of acute cholecystitis in which patients are operated upon within 48 hours of the onset of their pain. Such patients reveal at operation tensely distended, edematous, red gall bladders. Yet their course following immediate cholecystectomy is generally very much like the course of any laparotomy for a non-inflammatory lesion. In some respects the early case of acute cholecystitis resembles that of the early case of an ovarian cyst with a twisted pedicle. Basically, the pathology of the two conditions is an interference with the blood supply of an intraperitoneal viscus. In each case, therefore, immediate surgery is a logical procedure. In neither situation, certainly, is the fundamental pathology a "septic process."

A recent study of a series of cases of acute cholecystitis has impressed me with the advantages of the immediate over the delayed operation. By "immediate operation," I refer to operations, usually cholecystectomy, carried out within 2 to 3 days of the onset of pain. It is perhaps unnecessary to say that in every one of these cases there is always time to prepare for this surgery by the administration of fluids and glucose. In my experience, when operation has been done within 48 hours of the onset of the attack, complications are few, hospital stays are short, and there is no mortality. When the operation is performed late in the disease, complications due to infection are common, perforation is found in 14 per cent, hospital stays are long, and secondary operations are often necessary.

It is my belief that cystic duct obstruction is the first event in the pathological process of acute cholecystitis and that infection, when it is present, is secondary to cystic duct obstruction. Immediate removal of the gall bladder, therefore, in the early cases of acute cholecystitis seems indicated as soon as the

diagnosis is apparent and before infection, with its complications, has appeared.

HOWARD M. CLUTE.

CONCERNING THE TERM "SHOCK"

IT IS one of the common generalizations of economics that money of low value drives out of circulation that of higher value. Similarly in the use of words, those with a low content of precise meaning and therefore widely applicable, frequently displace those more accurate terms which are more limited in scope or at least impede the introduction of such. Some words have a specious appearance of precision and in that respect resemble counterfeit money, and one of these is the term "shock."

Defining a word serves the same purpose as assaying the metallic content of a coin and will frequently disclose the baseness of its content. In attempting to do this with "shock," it is soon discovered that it only represents a congeries of symptoms and signs which is characteristic of no one mechanism or etiological factor, without it be the condition of the observer's mind. It is in short one of those words "which cloak the unknown in the indefinable."

Yet the fact that it is in current and common usage signifies that it meets some demand—a demand which should be satisfied by a more cogent term.

In the early nineteenth century when "shock" began to be more intensively studied with the resulting popularization of the term, the concept was broadened by Romberg beyond the common idea that it was associated only with surgery, by indicating that it was in essence a failure of the circulation of the blood which occurred as a terminal phenomenon in many diseases including those caused by specific

infectious agents. Recently this same concept has been revived and given the horrific name of "medical shock," which distributes the disgrace of the term even more widely.

During these years, as the result of many investigations, it has come to be understood that failure of the circulation of the blood is usually due to either a deficient propulsive force—cardiac failure—or inadequacy of the distributive apparatus, that is to say, vascular failure. That the latter is most frequently due to a decrease of blood volume as a result of

the inability of the blood vessels to retain all or some of the components of its contents does not invalidate the significance of the term, vascular failure.

It would seem reasonable then to abandon the inexact and misleading word "shock" and replace it with *cardiac failure* or *vascular failure* depending upon whether the propulsive or the distributive mechanism is primarily involved. With either of these, the causative factor may be named so as to complete the picture.

FAMOUS AUTOGRAPHS

THREE DOCTOR WILLIAM BEAUMONT LETTERS

ARNO B. LUCKHARDT, Ph D, Chicago, Illinois

MANY of the biographical sketches of Dr William Beaumont that have appeared from time to time and are still appearing, though interesting and stimulating, consist essentially of a reiteration—sometimes almost *verbatim*—of previous authors. The legend, and lore, and the facts concerning William Beaumont will bear repetition.

From the Physiological Laboratories, The University of Chicago

The interest taken in him and his accomplishments are highly commendable. This man, whose achievements merit canonization as the patron saint of American Medicine, has been sadly overlooked by the profession. He will always remain a model for bed-side solicitude, self-sacrifice, research in the clinic and laboratory, and accomplishment under trying conditions that required dogged persistence and the necessary drive to carry on in spite of the

Facsimile of letter written by Wm Beaumont in January of 1850
His irritation at insult to his profession is very evident.

St Louis Mo

Mar 4 1867

Yr Maddy of 16th Nov is just a 3 and 4 year
part covered with spunk - toothache

I shall send myself to you directly
and embrace the 10 last opportunity of forming
you sufficient authority to locate the Missouri
for a 3000 dollars each upon the last found
you can in the Military Reserve at St Louis
and anywhere or any other eligible land in the
State. But the better to secure a good land
time I will suggest that you go on, which
the last date you can expect. Watch your
steps, build a happy home or elsewhere
for 1000000 dollars. The year answer the
Maddie to cover the house or insurance
Conclude and thank Henry Althoff
or Mr. Althoff on the subject in

I forwarded my claim in due form
for my 1000000 dollars after the last was
forwarded to the proper Department. The letter
sent to the Com of Genl M. Charles who
presented them in person and made favorable
report and I am doing upholding the Missouri
-1000000 dollars - 1000000 - I have as yet
shall send them over to you with instructions

It would be time my business I shall
come over this spring. If I can not your
mother will most likely come with them
and I may come after

Yours, J. M. White has also been
rid and passed with much pleasure and
satisfaction. I shall write you again
soon in answer to your inquiries &c.

We are all pretty well now -
have been a little unwell with bad colds,
a week or two since -

Love to you all. Let me
hear from you often and believe me
Yr affectionate
Father

Missouri

irresponsibility and untrustworthiness of Alexis St. Martin, and the obstacles furnished by nature and the malicious designs of members of his own profession

These letters, represent a psychological cross section of the man, Beaumont, in several moods. One of them Dr. Beaumont wrote while irritated because he felt himself insulted professionally, the second, gives ample evidence that Dr. Beaumont was possibly not naive in business matters, and the last, in simple transcription, is a Christmas letter to his son, Israel Green Beaumont, which ends with an improvised poem portraying the affectionate father.

These letters are a part of an invaluable collection of Beaumontiana consisting of letters, personal effects, and various documents which will throw new and interesting light on Beaumont, his family, friends, business and military associates, and on the times in which he lived. During the spring of 1936, the University of Chicago was made the beneficiary, through the generosity of Mr. and Mrs. E. A. Beaumont, of DePere, Wisconsin, of this documentary material, which permits of a new and better evaluation of America's "Backwoods Physiologist."

Saint Louis, Missouri

Christmas Eve

Dec. 25, 1850

A merrie morrow to you—Bud—and may you enjoy it right merrily and morally with all our relations and friends there

And now you are on the spot and no doubt competent and feel confident in your own judgment, aided if necessary by timely counsels of your friends to manage my interests at the Bay for our mutual benefit and satisfaction

I shall submit the following subject and suggestions to your and Uncle Tommy's consideration and disposal — (Then follows directions relating to the handling of certain real estate located at Green Bay.....)

If you prove yourself pretty shrewd and discrete in this, I shall probably afford you other opportunities to exercise and improve your business faculties in the disposal of other parts of the property next season. I can add nothing to the information of my last a few days since. All in health and everything as usual.

Christmas has just come—and I must-go-to-bed 12½ O'clock a.m. and all the rest are asleeping—your Father-just-agoing—nod-ding—go-i-n-g-to-slee-p."

6 o'clock morning—all wide awake—

And kissing—for old Nick's sake—

Lapping lasses and Buckwheat cakes,

Sipping coffee—eating venison steaks—

Oyster soup and chicken fixings—

Hot rolls and butter made from strippings

Let us hear of your doings soon, and gratify your father

W B

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

AN excellent review of what is at present known of the physiology and clinical endocrinology of obstetrics and gynecology is presented by Kurzrok in his recent book.¹ Each section is followed by a valuable bibliography. The first third of the work is devoted to the physiology and chemistry of all the endocrine glands. The endocrinology of menstruation, ovulation, uterine motility, pregnancy and lactation is then discussed. Much of the author's own work has had to do with hormone assay in clinical ovarian syndromes. Hence, the chapters on amenorrhea, functional uterine bleeding, dysmenorrhea, the menopause, the toxemias of pregnancy, precocious maturity, intersexuality, and sterility are particularly interesting. Case reports include the results of hormone titrations. The book concludes with a chapter on methods of hormone assay.

One pleasant quality of the work is the frankness with which ignorance is admitted. As a result the author is able to indicate the next steps to be taken in research. Thus many problems are suggested. The approach to the clinical diagnosis and therapy is by definite deduction from established physiology. Hormone assay is used to demonstrate the functional relationships which exist in the patient. As a result this volume marks a definite advance over other endocrine treatises recently published.

PAUL STARR

¹THE ENDOCRINES IN OBSTETRICS AND GYNECOLOGY. By Raphael Kurzrok, Ph.D. M.D. Baltimore: The Williams & Wilkins Co. 1937.

A SMALL, well bound volume, well printed on good paper, is *Practical Talks on Kidney Disease*.² The book is broken into the usual topics when renal and vascular diseases are discussed. The author states that "this small volume is designed to assist the physician who practices general medicine to understand what is generally regarded as a difficult and confused subject. It is not intended as a monograph or text book." The author further states that he is "aware of the dangers in attempting to deal simply with such complex subjects and I plead guilty to many errors of omission which, however, can be easily corrected by further reading in certain books from which I have borrowed freely." The latter statement covers the main fault of the book. The material is incompletely and casually presented so that one seeking aid would be generally disappointed. General practitioners who are interested in therapy will not find an organized or aggressive program.

The author properly warns against the careless use of large doses of acid or alkali producing salts because of the ease of disturbing acid base equilibrium. He also ridicules the assaults which have been made all too frequently upon the hypertensive individual by needless dietary restriction, tooth extraction and like procedures.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

An excellent review of what is at present known of the physiology and clinical endocrinology of obstetrics and gynecology is presented by Kurzrok in his recent book 'Each section is followed by a valuable bibliography. The first third of the work is devoted to the physiology and chemistry of all the endocrine glands. The endocrinology of menstruation, ovulation, uterine motility, pregnancy and lactation is then discussed. Much of the author's own work has had to do with hormone assay in clinical ovarian syndromes. Hence the chapters on amenorrhea, functional uterine bleeding, dysmenorrhea, the menopause, the toxemias of pregnancy, precocious maturity, intersexuality, and sterility are particularly interesting. Case reports include the results of hormone titrations. The book concludes with a chapter on methods of hormone assay.

One pleasant quality of the work is the frankness with which ignorance is admitted. As a result, the author is able to indicate the next steps to be taken in research. Thus many problems are suggested. The approach to the clinical diagnosis and therapy is by definite deduction from established physiology. Hormone assay is used to demonstrate the functional relationships which exist in the patient. As a result this volume marks a definite advance over other endocrine treatises recently published.

PAUL STARR

THE ENDOCRINE IN OBSTETRICS AND GYNECOLOGY By Raphael Kurzrok Ph.D. M.D. Baltimore: The Williams & Wilkins Co. 1937

A SMALL, well bound volume, well printed on good paper, is *Practical Talks on Kidney Disease*. The book is broken into the usual topics when renal and vascular diseases are discussed. The author states that this small volume is designed to assist the physician who practices general medicine to understand what is generally regarded as a difficult and confused subject. It is not intended as a monograph or text book. The author further states that he is aware of the dangers in attempting to deal simply with such complex subjects and I plead guilty to many errors of omission which, however, can be easily corrected by further reading in certain books from which I have borrowed freely. The latter statement covers the main fault of the book. The material is incompletely and casually presented so that one seeking aid would be generally disappointed. General practitioners who are interested in therapy will not find an organized or aggressive program.

The author properly warns against the careless use of large doses of acid or alkali producing salts because of the ease of disturbing acid base equilibrium. He also ridicules the assaults which have been made all too frequently upon the hypertensive individual by needless dietary restriction, tooth extraction, and like procedures.

CLINICAL BEHAVIOR OF EARLY CARCINOMA OF THE CERVIX

WALTER SCHILLER, M D, New York, New York

EIGHT years ago, I made the first report on my study of the histological and clinical diagnosis of early carcinoma of the cervix, the pathological importance of the carcinomatous layer, and the possibility of establishing the diagnosis by means of the iodine test. Since this report the method has been tried by many gynecologists and pathologists both in Europe and America. In the United States numerous workers, among them Baxter, Emmert, Galloway, Graves, Henriksen, Martzloff, Norris, Schmitz, Sturgis, and Whytock have reported good results with the iodine test. Stearns, of the University of Nebraska, however, reported negative results in a series of 200 cases, but negative results in such a small series do not prove anything. Soon after publishing his report, Stearns informed me that he found a small leucoplacic area on the cervix of a 32 year old woman who complained of vaginal discharge. Biopsy revealed the smallest carcinoma ever diagnosed at the pathological Institute of the University of Nebraska. On a recent visit to Omaha I had an opportunity to see the microscopic section and found it to be a typical, beginning carcinoma with the characteristic oblique line of demarcation. Beattie, of England, Forgue, Pauchet, and Pouliot, of France; Coghlan,

of Australia, and Vogt, of Germany; as well as Boschetti, Casati, and Cuizza, of Italy, report good results and strongly recommend the iodine test as an aid in the diagnosis of early carcinoma of the cervix.

I am in a position to report 43 cases that have been observed for at least 5 years or more after operation. In all of them, iodine tests were made and revealed suspicious appearing patches on the cervixes. Subsequent microscopic examinations of tissue removed established the diagnosis of beginning surface carcinoma of the cervix. In only 1 of these 43 patients was there a recurrence. Therefore there were absolute cures¹ in 98 per cent of the cases. The patient with the recurrence died from paravertebral gland metastasis and there were also symptoms of compression of the large vessels. The case is of special interest because of the peculiar location of the metastases. The patient did not receive postoperative radiation treatment.² Examination of the extirpated uterus showed a superficial carcinomatous layer on the cervix. In one area there was typical, yet initial, invasive growth along and next to the glands of the cervical canal. The tumor was highly malignant. This

¹The cases have now increased to 51. Of these there was 1 recurrence and patient died and 1 recurrence and patient lived and is being treated with irradiation. In other words there were 49 cures in 51 cases.

²Reported by Kermanner in Halban-Seitz, vol 4 p 818, by the author in Arch f Gynaek., vol 133, p 277.

case did not exactly fit in with the classification of beginning carcinoma, the criteria of which were established later. Failure in this case does not rest entirely upon the diagnostic method used. It is true that in patients operated upon less than 5 years ago, there were 2 recurrences. The other cases in the series can not yet be declared "cured" as the 5 year period has not yet elapsed. The clinical failures in these 2 cases support the original histological diagnosis and prove that diagnosis of carcinoma from a superficial growth is justifiable.

Following is the report of a case

Antonie N., aged 59 years. Menstruation began at 16 years, was regular and of normal cycle. Patient had had 3 deliveries, no abortions. Menopause began 7 years ago. Patient complained of slight vaginal bleeding which lasted 1 week.

Examination revealed ptosis, cystocele the size of an apple, moderate rectocele, the uterus retroverted, hard, movable. An erosion was noted on the posterior lip and a healing erosion on the anterior lip. Painting of the cervix with iodine revealed two white patches, the larger patch on the posterior lip. Biopsy of the white area revealed an extensive superficial carcinomatous epithelium on an inflamed stroma. Operation consisted of vaginal extirpation of the uterus without the adnexa, anterior and posterior colporrhaphy with extensive resection of the vagina. Histological examination of the extirpated uterus revealed on the cervix extensive carcinomatous surface epithelium (Figs 1, 2, 3, 4 and 5). Patient was given three series of x-ray treatments and was examined again in February, 1936. At this time there were found brittle easily bleeding tumor masses at

the blind end of the vagina. Rectal examination elicited a definite sensation of an infiltrating mass reaching to the left pelvic wall. Biopsy showed the characteristic carcinomatous epithelium of comparatively great maturity, polymorphous nuclei and numerous mitotic figures. Patient was given 2 ray treatment and additional radium.

This case shows definitely that even when the growth extends only slightly into the tissues and a relatively radical operation is done, recurrence is possible. In this case the growth did not extend beyond the depth generally found in the third state of healing erosions. The small surface extension of this carcinoma was much greater than its invasion, but in spite of this fact recurrence took place. In their report of 16 primary cancers, Smith and Pemberton describe cases similar to this one, but they do not give exact data as to the size of the beginning carcinomas. Their photomicrographs prove beyond doubt the carcinomatous character of the lesions in their cases. However, they do not show whether the lesions had invaded the tissue or whether the area involved was great. Recurrence in some of these cases proved that the pathologists were wrong in their diagnoses of atypical epithelium without malignancy.

All patients in my series of beginning carcinoma were subjected to operation, that is extirpation of the uterus, as a rule the Wertheim operation. The limited extent of the

carcinoma and the high percentage of young women affected—and this percentage seems to be increasing, according to our latest experiences—make less radical treatment very desirable. Sufficient time has not as yet elapsed to report the results in the treatment of beginning carcinoma. Of the cases of Smith and Pemberton 6 patients were treated by trachelorrhaphy only and there were 4 recurrences. The 2 others have been observed one for 3 years, the other for 15 months only. Nine of the patients were treated by means of excision, cauterization, or trachelorrhaphy, plus subsequent application of radium. Of these 9 patients, 8 remained cured, 4 patients having been observed over a period of less than 5 years. The impression seems to be gained from this series of cases that radium treatment greatly improves the prognosis.

Schmitz published the report of a case of amputation of the cervix in which an early carcinoma had been overlooked. Recurrence took place and healing was effected with radium. Simple amputation of the cervix is evidently not sufficient in most of the cases, especially not a low or flat amputation. Even after a high Sturmdorf amputation, recurrence will take place in some cases, because the carcinomatous surface epithelium reaches high up into the cervical canal, and the amputation has not been done well within the normal tissue. Radium application in the cervical canal destroys carcinomatous layers, with certainty, even those extending up to the internal

Fig 3 Normal epithelium, left, carcinomatous layer, right. The beginning inflammatory infiltration of the stroma coincides with the carcinoma. $\times 60$

os. The fact that recurrences sometimes follow removal of superficial carcinomatous layers which do not invade the deep tissues justifies the theoretical basis on which the early diagnosis of carcinoma is made, namely, that carcinoma of the cervix begins as a superficial layer without any downgrowth invasion. The application of iodine to the cervix makes the lesions visible to the naked eye, thus facilitating the early diagnosis. The reaction is not a specific one, but the use of iodine is a rapid and practical way of finding suspicious alterations that might otherwise escape the examiner. Microscopic examination of tissue from the white patches is necessary to establish a definite diagnosis.

That carcinoma may be present as a superficial layer only without invasion of the deeper

Fig 4 Carcinomatous layer of the posterior lip, a poorly demarcated plug creeps into the depth. $\times 95$

Fig 5 Carcinomatous layer of the posterior cervical lip. $\times 95$

tissues is now an almost generally accepted fact. Authors who do not make a definite diagnosis of carcinoma unless there is evidence of an invasive growth (Franque and occasionally Hinselmann) designate these superficial carcinomas as "carcinoid" or "precancerous" tissue but clinical treatment is given the same as for malignant growths. From a practical point of view, these differ only in that they use a different terminology and do not feel justified in diagnosing carcinoma on the cytological character of the epithelium only. To bring the two conceptions together would be desirable for the following reasons. Biopsy makes possible examination of only a small piece of tissue. It occasionally happens therefore that one specimen of tissue removed contains none of the malignant lesion while a second specimen or the gross specimen itself if operation is done will reveal an invasive growth close to the area affected by the surface lesion which was noted in the first specimen.

In such cases the authors who use the terms "carcinoid" and "precancerous" for surface growth without deeper invasion would discuss the condition as follows. The first biopsy shows precancerous or carcinoid surface epithelium, therefore, it is possible, even probable, that the tissue in the nearby area contains fully developed carcinoma with deeper invasion. This possibility or probability not only justifies but necessitates the use of measures as radical as would be used if the first biopsy had shown carcinoma already invading the deeper tissues. Thus they use the same treatment for "surface layer" carcinomatous lesions as for carcinoma already affecting the deeper layers. Therefore I believe it would be a step forward if the pathologists would classify both types of lesions as carcinoma.

In the rare case a small patch of carcinomatous epithelium is present but the superficial carcinomatous layer is very extensive and one or both lips of the cervix may be involved before there is any significant ulceration. In such cases, the surface epithelium is not so transparent or shiny as normal but it is not eroded or ulcerated. Unless colposcopic examination is done or the iodine test is used, these lesions may be easily overlooked. Microscopic examination of the surgical speci-

men in such a case may show a surprising amount of invasive growth which sometimes reaches as far as the isthmus or the corpus. The invasion is not general, it may be present in one or two places, usually near the external os. Sometimes it is necessary to make serial sections to locate the area in which the carcinoma broke into the deeper layers. Of the three characteristic properties of carcinoma—superficial growth, invasion, and ulceration—this type possesses chiefly the first two. To a certain extent these lesions resemble the endophytic carcinoma without superficial ulcerations as are sometimes found in the presence of prolapse.

Hoegler reported a case of prolapse in which a carcinomatous layer of the cervix developed from slightly eroded hyperkeratotic epithelium, which in turn gave rise to a carcinoma extending up to the fundus. I reported a case without prolapse in which the carcinomatous layer affected the cervix but did not invade the deeper tissue and there were no ulcerations.

A brief report of another case characteristic of this type follows.

M. F., aged 43 years. Menstruation began at 13 years, occurred every 4 weeks, lasted 3 days, and was regular. Patient had had 3 spontaneous deliveries, no abortions. For the past 4 months the menstrual period had been prolonged to 1 week and bleeding had increased.

Examination revealed an edematous mons, left thigh edematous, skin tense. The vulva gaped and there was a moderate cystocele. The uterus was enlarged, hard and movable, the left parametrium was hard with cord-like infiltrations, the cervix was smooth and plump. Pieces of endometrium and a small piece of typical carcinomatous surface epithelium with cervical glands opening through were obtained from curettement.

At laparotomy a fairly enlarged uterus was found and there were several flat white areas of metastases on the parietal peritoneum, two fingers to the left of the uterus. A node the size of a walnut was noted in this area. Examination of the extirpated uterus showed the presence of a circular carcinomatous layer affecting the whole cervix and around the external os, a small area of glandular inflammatory eroded tissue, part of which was covered with carcinomatous epithelium which plugged some of the cervical glands—resembling normal epithelium in the third stage of healing. Next to this the stroma of the portio was free of carcinoma. Higher up in the wall of the cervical canal there were numerous small patches and trabeculae of carcinomatous tissue. Mc-

Fig 6 Low power Carcinomatous layer (black) on the surface of the portio, carcinomatous plugs are noted in the lymph vessels and perivascular lymph spaces of the portio stroma $\times 5$

tastases filled the lymph spaces, especially those around the large arteries. Near the cul-de-sac of Douglas the areas of metastases increased in size, to form large, partly solid, partly reticulated masses (Figs 6 and 7). It seems that the carcinoma here perforated through the peritoneum and had formed the deposits which were noted during the operation.

This case is an example of a generalized, spreading carcinoma which had no superficial ulcerations, but which had developed from a small area of invasion. A biopsy specimen from any part of the cervix except a small area at the external os would have revealed nothing but a so called superficial layer without invasion and yet it was found to be an advanced inoperable lesion.

The basis for our theory is that carcinoma of the cervix is of superficial and not of deep origin. The earliest phase of the carcinoma is the *superficial carcinomatous layer*. To Kermanner and Schottlaender (1912) goes the credit for recognizing it as a *special form* of growth in some advanced cases of uterine carcinoma. Their predecessors, Pronai and

Fig 7. Carcinomatous layer of the portio covered with a thick layer of parakeratosis $\times 95$.

Schauenstein, described only a few cases. Kermanner and Schottlaender, however, did not identify specifically the surface layer next to the area containing the advanced stage carcinoma in primary uterine cancer, the presence of which I was able to prove. Today many workers discard the old criteria in arriving at a diagnosis of uterine carcinoma and base their decision on the type of cell alone, even though the cancer cells are noted only in the superficial layers (Keller and Van de Vyver, Graves, Freedman, etc.). Broders (1932) found in the epithelium of the larynx, mandible, skin, rectum, and other organs, deep invasive epithelial changes of benign character as well as superficial changes of malignant character.

The iodine test makes it possible to diagnose the presence of carcinomatous layers clinically, thus making early treatment possible. The value of this test is evident in the reports of cases in which the patients were treated for early carcinoma. The diagnosis of very early carcinoma of the cervix can be made only in patients who are examined for some other illness or who make it a practice to have periodical gynecological examinations.

In a review of early carcinoma cases¹ I made a special study of the objective signs and subjective symptoms; unfortunately a single specific sign or symptom was not to be found. The characteristic syndromes of advanced

¹Wien. med. Wchnschr., 1931, No. 36.

Fig 8 Carcinomatous layer with 2 thick plugs the one on the left shows that central disintegration has taken place $\times 150$

Fig 9 Low power Cervical canal just above the external os a carcinomatous layer is present on the anterior lip $\times 5$

carcinoma—anemia, loss of weight, etc—are absent. These signs are probably sequels of advanced carcinoma, not precursors of primary carcinoma. Some of our younger patients with primary carcinomas were in excellent physical condition. The only specific symptom found in some of the cases was contact bleeding. This was noticed even in patients in whom the carcinomatous layers were only a few square millimeters in size. The cause of this bleeding is the brittleness of the carcinomatous epithelium, the atypical basal cells of which are not in firm contact with the underlying inflamed stroma. It can be stated with certainty that early carcinoma of the cervix as a general rule does not produce subjective symptoms or illness which would cause a patient to see a gynecologist.

At the present time a study is being made of the latent period in cervical carcinoma—that is, the interval between the true onset of the carcinoma and the appearance of noticeable signs and symptoms. According to Fesch, Goecke, Stahler, and others, the latent period may last several months. However, their methods of diagnosing carcinoma in an early stage differs completely from that of Hinselmann, Graves, Pemberton, Smith, Beattie, and myself. Carcinoma designated 'early' by Fesch and others is far too advanced to be compared with the early carcinoma detected by means of the iodine test. The classification

of Goecke does not include the lesion found in the true initial stage. The classification of uterine carcinomas as proposed by the Hygiene Committee of the League of Nations, completely ignores the early stages. According to this classification, there are four phases of uterine carcinoma: (1) carcinoma limited to the uterus, (2) carcinoma with slight infiltration of the parametrium, (3) carcinoma with infiltration which is marked but which does not reach to the pelvic wall, (4) carcinoma with parametrial infiltration which affects the pelvic wall and in which eventually metastases appear.

The duration of the "early stage" is important from the therapeutic point of view. If the 'early stage' (superficial carcinomatous layer) were of several days' or weeks' duration only, then the chances of early diagnosis would be very small, it would be difficult to make early diagnosis the rule for that would require systematic, periodical examinations, an impractical requisite if the intervals between examinations were too short (1 or 2 months). It is believed, however, that the primary phase is of long standing. The histological resemblance between early carcinoma of the cervix and Bowen's dermatosis might be mentioned. Bowen's dermatosis differs completely from all other carcinomas of the skin because there is such a long interval between the superficial and the invasive growth. At first Bowen's

Fig 10. A carcinomatous layer with large, plump plugs growing toward the cervical glands $\times 21$

Fig 11. Carcinomatous layer with a deep fold on the left; in the center there is a plug growing toward a cervical gland. Note the polymorphous and atypical cells and the frequent mitosis $\times 110$

dermatosis was not considered as carcinoma of the skin because it was not known that the superficial lesion became invasive only after a latent period of several years. In the usual type of carcinoma of the skin the surface phase is so short that the lesion is seldom diagnosed before it has penetrated the deep tissues.

Since Bowen's dermatosis morphologically resembles early carcinoma of the portio, it is likely that the two also have some biological properties in common, for instance the long phase of surface growth. This cannot be proved by clinical observation, however, because as soon as it is determined that a carcinomatous layer of the cervix is present it is our duty to treat the lesion radically, whether we regard it as carcinomatous or precarcinomatous, the carcinomatous layer must be removed or destroyed well into the healthy tissue, through amputation of the cervix, total extirpation, or radium treatment. Therefore, it is impossible to say how long it would have taken for the surface layer to send trabeculae or plugs into the depth. Lesions properly diagnosed and properly treated throw no light on the subject. It is only in the cases classed as failures, clinically, that we can obtain some information; for instance, in the first biopsy a malignancy may not be recognized but it may be noted in a later examination. In such a case, we can compare the sections from the two examinations and note the process of growth. Again some patients refuse treatment after a definite diagnosis has been made. Later these patients may again seek advice and we then have the opportunity to investi-

gate and note any changes which may have taken place in the lesion during the interval.

To make these two sources of information of any value, one condition must be fulfilled, that is, the carcinomatous tissue must not be entirely removed at the first biopsy. In my experience complete removal of the pathological tissue is seldom accomplished. If tissue is removed from a carcinomatous layer several millimeters thick, it is true that in a relatively short time the tissue will replace itself. Let us consider the non-radical operations for malignancy. If the smallest piece of tumor tissue remains it will cause a recurrence if sufficient time elapses for it to develop. The same is true also of surface carcinoma. Experiments have shown that when a small piece of epithelium is removed from the cervix regeneration takes place in a short time. We know that epithelium with so marked a tendency to grow as is ascribed to carcinoma, is able to replace itself in a short time.

If we assume, in a special case, that the entire suspicious appearing tissue has been removed through biopsy and if later examination reveals the presence of carcinomatous tissue, there is only one explanation, namely, that a primary carcinoma has appeared a second time at the site of the first carcinoma. This assumption has been made several times by Smith and Pemberton (Case 15), by Hinselmann, and by Kamniker, but they did not

Fig 12 Low power biopsy specimen To the right from the midline a gland orifice is breaking through a carcinomatous layer (black) $\times 75$

Fig 13 A carcinomatous layer of tissue which was found penetrating into the depth alongside of a gland $\times 110$

prove that the original carcinoma was radically removed, without such proof the idea of the repeated production of carcinoma at the same site deserves no credit

Local recurrence after removal of an advanced carcinoma is never regarded as a secondary independent growth, but as the result of incomplete removal of the primary carcinoma¹

The 3 following cases are presented as examples of so called clinical failures in 2 of them carcinoma was not diagnosed at biopsy, in the third case carcinoma was diagnosed but the patient refused treatment In the first 2 cases there were failures in diagnosis but in each there is an explanation, even an apology In the second case a microscopic ex-

amination was made in 1923—before our method of diagnosis had been established In the first case examination was done by a substitute whose experience was not sufficient to enable him to settle so difficult a problem in diagnosis In both cases the diagnosis was "suspicious" of malignancy only and adequate treatment was therefore not carried out

Anna J aged 34 years Menstruation began at age of 13 years was regular until 6 years ago when it became irregular, every 3 or 4 weeks and the flow was scanty Patient was a tripara Last parturition occurred 7 years ago and there had been an abortion without any complications 6 years ago Patient came to the clinic because of a 6 months period of amenorrhea Biopsy specimen was taken from a suspicious appearing area on the portio The gynec-

¹The same explanation must be used for the primary carcinoma.

Fig 14 Low power On the posterior lip a carcinoma (black) is disintegrating through inflammation The anterior lip is normal $\times 4$

Fig 16 Three small carcinomatous plugs between cervical glands $\times 66$

cologist found a suspicious area on the cervix. The substituting pathologist made a diagnosis from the biopsy specimen of atypical epithelium, possibly suspicious of carcinoma. But the slide showed characteristic carcinomatous surface epithelium with the typical demarcation line between the normal and the carcinomatous epithelium (Fig 8). After curettage and radiation treatment of the pituitary body the patient was discharged and 6 months later she was menstruating again. Sixteen months after the first examination the patient returned. The suspicious area had not changed in size or appearance. Careful re-examination of the original biopsy specimen as well as of new material showed definite carcinoma cells. A Wertheim operation was performed. Sections of the extirpated uterus showed a typical, superficial carcinomatous layer at the external os. This growth projected somewhat into the cervical

Fig 18 Carcinomatous layer, horizontal section, note the polymorphous cells and the irregular distribution of the nuclei $\times 110$

Fig 17 a, left. Portio with indistinct, blurred patches around the external os b, The same area after iodine application. A triangular, sharply demarcated, white area of leucoplacia (carcinomatous layer) is noted. On the posterior lip arranged in a circle, are several bright, yellowish-brown, poorly demarcated leucoplacic areas (histologically leucoparakeratosis). To the right of the os are 4 bright spots, which correspond to cystic glands. Repeated examinations showed that the leucoplacic areas which corresponded with the carcinomatous layer remained unchanged; the areas of leucoparakeratosis changed in appearance and size.

canal and reached into the depth along with some glands. Scattered among the normal epithelium there were short plugs which shut the gland openings and resembled erosions in the third stage of healing. The cytological structure, the very polymorphous and hyperchromic nuclei, the numerous giant cells, and the areas of crowded atypical mitosis made the diagnosis of carcinomatous layer certain. The most invasive plug was slightly over 1 millimeter in length. In the 16 months between the first biopsy and operation there was hardly any significant spread of the carcinoma, either on the surface or deep in the tissues (Figs 9, 10, 11). The lesion did not extend beyond the downgrowth of the normal epithelium in the neighboring erosion.

Elizabeth S., aged 38 years. Menstruation began when patient was 16 years of age, occurred every 4 weeks and lasted 6 to 7 days. She had had 3 normal deliveries with no abortions. For the past year the periods had been irregular, for past 6 months there

Fig 19 Inconstant area of leucoparakeratosis (right) of anterior lip changing into hyperkeratosis with keratohyaline layer (left)

had been slight contact bleeding and yellow discharge. Patient missed one period and wanted to know if she was pregnant.

Examination January 31, 1923, revealed a small cystocele, retroverted and somewhat movable uterus and the left adnexa thickened and tender. On both cervical lips there were small erosions. Tissue the size of a pea was taken from the erosion of the anterior lip which appeared suspicious of malignancy, because of its rough appearance. Biopsy revealed a glandular inflammatory, partly healing erosion. The squamous surface epithelium was partly shed at the edge of the slide; only there was a small piece of stratified epithelium—diagnosed "not suspicious." The patient was treated with topical applications of pyrolysic acid and was discharged. Examination 7 months later revealed a 3 months old pregnancy. She was delivered at term without any complications. Six years later she again went through a normal pregnancy. Both times she was delivered normally at home. One year after her last delivery she returned to the hospital because of a slight contact bleeding. Upon examination a small cervical polyp and a slightly bleeding eroded area on the anterior lip was found. The erosion could not be broken through by a probe (negative Chrobak test). Scrapings from the lesion definitely established the diagnosis of a superficial carcinomatous layer. The piece of tissue excised at the first examination was mounted on paraffin, and cut into serial sections. Careful study showed a small area of carcinomatous tissue in the eroded glandular area which reached to the edge of the block, thus showing that it had not been radically removed (Figs. 12, 13). In view of the old and the new findings the uterus was extirpated. Sections through the cervix showed a narrow strip of carcinomatous tissue in the region of the anterior lip. The carcinomatous tissue was resting on an inflammatory stroma partly extending over a glandular inflammatory eroded area. There were several small cones extending into the depth along the cervical glands, the longest of these did not exceed 1.2 millimeters. The findings in this case are more remarkable than in the first case. At the time of the first examination there was a small superficial carcinoma proved by the serial section. This was partly removed though not completely through removal of the biopsy specimen. Nine years later the patient was operated upon. During this interval she went through 2 normal pregnancies and in spite of this the carcinomatous layer did not make very significant progress (Figs. 14, 15, 16). The invasion into the tissue was no deeper than the normal epithelium in the area of the healing erosion.

The third case belongs to the second group. Carcinoma was diagnosed but the patient refused operation.

Maria C. aged 45 years. Menstruation began when patient was 13 years old, was regular, occurred every 4 weeks, and lasted 3 to 4 days. Last men-

strual period occurred 3 months ago and patient wants to know whether she is pregnant or not. Upon examination the following was found: a somewhat enlarged hard uterus anteflexed, slightly movable adnexa and parametria negative. On the right side of the anterior lip there was a small, oval shaped sharply defined area, the epithelium in this area appeared somewhat elevated and dull. Iodine application revealed a white sharply defined area of leukoplakia on a dark brown cervix. Scraping from the edge of the lesion showed a typical carcinomatous growth with polymorphous cells, hyperchromatic nuclei and atypical mitosis (Figs. 17, 18, 19). The patient refused operation or any other treatment in spite of repeated warnings. Eighteen months later we prevailed upon her to return for an examination. Surprisingly enough, we found that the carcinomatous lesion had not changed either in appearance or in size. Comparison between a sketch made at the first examination and the present condition definitely proved that the small surface carcinoma had remained stationary during the 18 months period. The part removed at the first curettage had been restored yet with no increase in size. The second biopsy showed carcinomatous surface epithelium of exactly the same type as that taken 18 months before.

SUMMARY

These 3 cases illustrate clearly that there is not only a biological but a morphological analogy between early carcinoma of the cervix and Bowen's dermatosis. The period of surface growth is exceptionally long in both types of carcinoma. Months sometimes several years, pass before the surface carcinoma begins to penetrate the deeper tissues. The spread into the lumina of the glands should not be regarded as invasive because the normal epithelium has the same tendency in healing erosions. The two dimensional superficial growth of the carcinomatous layer also is very slow. Our cases show that many months may pass before there is any appreciable change in the size of the lesion. Rapid and excessive growth, which has always been ascribed to malignant tumors, apparently does not occur until the carcinoma has reached a definite size, a certain amount of superficial disintegration, and some invasive growth. This may be called the secondary stage (Paltauf) and is characterized by the spread along the lymph spaces and by way of the lymph vessels to the lymph nodes. In the primary stage the malignancy is confined to its primary site and is characterized by slow growth.

The primary stage of solid cervical carcinoma lasts several months, sometimes a few years. This fact that the primary stage of carcinoma of the cervix, which represents 90 per cent of all carcinomas of the uterus, lasts for some time makes early diagnosis possible. To make early diagnoses possible periodic examinations, at least twice a year, would be necessary. Periodic examination would guarantee a patient that in case she developed carcinoma of the cervix, the growth would be recognized as carcinoma at a phase early enough in development to assure permanent cure in probably 95 per cent of the cases.

NOTES ON CUTANEOUS HEALING IN WOUNDS

J HERBERT CONWAY, M D, New York New York

THE attention of the surgical world is so centered upon the serious problems of morbidity, mortality, and functional results of surgery that it may seem elementary to present the subject of the healing of the skin in clean incised wounds. However, in the course of examination of nearly 1000 healed wounds in the surgical follow up clinic of the New York Hospital, the variation in the degree of fibroblastic response in healing by first intention was so great that the subject was deemed worthy of study.

Excellent observations on the physiological rules governing the rate of cicatrization in wounds may be found in the experimental works of Carrel, Carrel and Hartman and DuNouy (4). These investigators have shown that a healing wound undergoes a latent or quiescent period which ends abruptly and is followed by a period of contraction. DuNouy (5) developed a mathematical equation by which the rate of healing in a given wound can be expressed, its normal course predicted, and the time of its completion forecast. Howes, Sooy and Harvey demonstrated by experimental work on animals that the tensile strength of a healing wound depends upon the firmness of fibroblastic response. The maximal strength of the wound, according to their studies is attained in from 10 to 14 days. It is well known that the rate of cicatrization as well as the extent of fibroblastic response varies in different individuals. Furthermore these variations may be influenced by alteration of certain external factors which are under the control of the surgeon during incision, suture and subsequent care of the wound. The experiments performed by Clark suggested to him that epidermization is unaffected by diet. Ebeling's work with experimental animals led him to the conclusion that increase in environmental temperature may accelerate the rate of cicatrization.

It is the purpose of this paper to point out that certain details in the technique of surgical incision and suture have a direct effect upon the degree of fibroblastic response in a clean incised wound and also upon the ultimate cosmetic result. This observation is based on the appearance of scars, photographed 1 to 3 years after

operation and consideration of the ultimate result in relation to the variations in the surgical technique employed.

TECHNIQUE OF INCISION

Incisions should be made parallel to Langer's lines of elasticity of the skin if minimal cutaneous cicatrization is desired and widening of the scar is to be avoided. In operations about the face and neck, the direction of these lines of elasticity is usually observed since they can be defined easily through facial grimace. However, in operations on the abdomen and extremities primary importance is attached to exposure of the wound and attention rarely is paid to the direction of the incision as regards cutaneous tension.

Lower quadrant abdominal oblique incisions. In Figure 1 is shown a photograph of an oblique right lower quadrant abdominal incision made for hernioplasty. The gradual widening of the scar toward the lower end of the incision is a common observation in wounds obliquely placed in this anatomical region. This photograph was taken 1 year after operation had been performed and the wound had healed *per primam*. It has been noted repeatedly that when obliquely placed lower quadrant abdominal incisions are made, they show a wider separation of the cutaneous margins at the lower end of the wound than in the upper portion. The variation in the degree of tension on the wound margins at the upper and lower ends is reflected in the greater width of the resultant scar in its lower portion. These observations have led me to the belief that the lines of elasticity of the skin run transversely in the suprapubic area rather than obliquely vertical as Langer's diagrammatic figure represents them. It is recalled that Langer's observations regarding cutaneous tension were made on cadavers. It is possible that the physiological elasticity of the various surface regions may be different in the living subject. Observation of 100 patients in whom oblique right lower quadrant incisions for appendectomy or hernioplasty had healed by first intention showed this same type of widening of the cutaneous scar at the lower end of the wound in 62. In 37 patients the cutaneous healing was ideal, fibroblastic response was minimal. In 1 patient, a tendency to keloid formation was manifested.

Fig 1

Fig 2

Fig 3

Fig 1. C A Photograph of scar taken 1 year after inguinal hernioplasty. Note the fine linear cutaneous scar in the upper portion of the wound and the widening of the scar to the width of 1 centimeter in the lower portion of the wound.

Fig 2. B S Variation in degree of fibroblastic response at different levels in the same incision. In the upper portion of the wound the cicatricial response is minimal and healing is ideal. In the lower portion the scar is hypertrophic. Operation was performed for gall-bladder disease. Photograph was taken 3 years after operation. The patient did not gain weight after operation. The wound healed *per primam*. It is believed that this variation in fibroblastic response can be explained only on the basis of variation in the technique of incision and suture at the

two levels in the wound. Probably this incision was beveled in the lower part and the cutaneous edges in that area were poorly approximated in the suture.

Fig 3. M R Photograph of scar of right rectus incision made for cholecystectomy. Photograph taken 2 years after operation. This patient did not gain weight in 2 year period after operation. Note the segments of fine linear cicatrix alternated with areas of hypertrophic scar. The upper segment with excessive reaction represents the point of emergence of the abdominal drain. The lower segment of hypertrophic scar can be accounted for only by beveling of the incision or by poor approximation of the cutaneous margins in the technique of suture. There was no infection and no separation of the edges of the skin after removal of sutures.

TABLE I.—OBLIQUE INCISIONS IN RIGHT LOWER QUADRANT OF ABDOMEN

Technique of incision of the skin. It is well known that it is important to hold the skin taut while it is being incised so that incision may be made sharply at a right angle to the flat cutaneous surface. If this technique is not followed the operator may divide the layers of the skin in an oblique plane—the so called “beveled” incision. It is difficult accurately to suture the edges of such an incision in close approximation.

Vertical incisions in the right upper quadrant of the abdomen. Diffuse widening of the abdominal scar to a width of 0.8 centimeter or more was

noted in 118 of 225 patients in whom vertical incisions had been made in the right upper quadrant of the abdomen in operations on the biliary tract. Additional factors which, it is believed, influence unfavorably the healing of wounds in this area are the increased mobility of the upper abdominal area due to respiratory movement and the tendency of many patients to gain weight after operation. It is felt that the constant motion of the upper abdominal wall may increase cutaneous tension and thus exert force on the line of healing at a time when the maximal tensile strength of the wound has not yet been reached. Postoperative gain in the weight of the individual is accompanied by an increase in the volume and depth of the panniculus adiposus so that cutaneous tension is also increased by this factor. An increase in weight of 10 to 30 pounds in the postoperative period has been considered sufficient to cause an increase in cutaneous tension in the region of the right upper quadrant wound.

THE ZENITH HOSPITAL

Fig 4

Fig 5

Fig 6

Fig 4 CT Scar of an upper right rectus incision made in operation for gall bladder disease. Here again the areas of hypertrophic scar are irregularly alternated with finely healed scar. Photograph taken 3 years after operation. The patient did not gain weight after operation. There was no infection and no separation of the edges of the skin after removal of the stitches.

Fig 5 OP Shows hypertrophied scar in the long leg of a hockey stick incision made for cholecystectomy. The small upper angulated portion of the incision has not formed hypertrophic scar probably because its direction more nearly parallels that of Langer's lines.

Fig 6 CS Scar of midline lower abdominal incision taken 4 years after operation. Note the fine linear cicatrix in the upper portion of the wound. The hypertrophic scar in the middle can be accounted for only by beveling of the incision or poor approximation of the cutaneous margins in the technique of the suture. The nodule of hypertrophic scar at the lower end of the incision represents a point at which minor infection with draining sinus was present. A catgut suture was expelled from this point. This type of localized nodular hypertrophic scar is often seen in wounds which have been sutured with catgut.

Fig 7 SR Photograph of a scar on the dorsal thoracic region resultant from the excision of an elliptical segment of skin and subcutaneous fat. The cicatrix has widened to 3 centimeters. Adequate mobilization of the lateral flaps by undercutting might have given more ideal cutaneous healing.

Of 118 patients whose scars showed diffuse widening, 89 had gained 10 to 0 pounds in weight while in 60 of the 84 patients who showed ideal linear scar formation there was no significant gain of weight.

	No. cases
Uniform widening of scar to 0.8 cm. or more	118
Ideal healing—minimal scar	84
Healing with irregular scar	23
Keloid formation	0
Total	225

In 23 patients irregular healing of the upper abdominal scar was noticed. It is believed that this segmental alternation of finely healed cicatrix with areas of hypertrophic scar is due to the following factors: infection at the point of emergence of abdominal drains; beveling of the incision; and irregular approximation of cutaneous margins in the suture of the edges of the skin.

Fig 8 Fine arterial silk used for approximation of the edges of the skin in wounds about the face is shown in comparison with the ordinary No 5 fine black silk. The material used for the crêpe lisse dressing is purchased at any department store as indestructible flat chiffon.

Lower abdominal vertical incisions In 25 mid-line incisions in the lower abdominal region, made for operations on the female pelvic organs, cutaneous healing was ideal in only 12. In none of the patients was diffuse widening of the scar noted as in the study of upper abdominal wounds. In the other 13 patients the scar showed segments of hypertrophic scar. All but 2 of these wounds were sutured throughout with catgut. The fact that a suture of catgut excites more cellular reaction than does a silk suture was pointed out by Halsted (7). Howes has recently demonstrated in experimental wounds that those sutured with silk showed fibroblastic proliferation earlier and the wounds accumulated strength more rapidly than did those sutured with catgut. The frequency with which these wounds, sutured with catgut, drain seropurulent material from small openings in them probably accounts for the irregular scar formation in these cases.

TABLE III—INCISIONS IN MIDLINE OF LOWER HALF OF ABDOMEN

Fig 9 A R. Photograph of scar taken 1 year after pericardiectomy. Note the hypertrophic scar in the upper transverse arm and the vertical portion of the incision. The lower transverse portion has healed without hypertrophic scar formation.

Cervical incisions Of 50 patients in whom the usual "collar" incision was made for thyroidectomy, healing was ideal in 41 patients. In the

TABLE IV.—CERVICAL INCISIONS ("COLLAR" INCISIONS FOR THYROIDECTOMY)

	No cases
Uniform widening of scar to 0.8 cm. or more	0
Ideal healing—minimal scar	41
Healing with irregular scar	0
Hypertrophic scar—slight	9
Keloid formation	0
Total	50

9 others there was slight hypertrophic reaction throughout the scar. In none of the patients was irregular cutaneous healing noted. The high percentage of cases in which healing was ideal is thought to be due to the fact that, in the technique of the suture of the "collar" incision, the

platysma muscle is neatly sutured in a plane separate from the line of suture of the skin and that cutaneous tension is relieved by the wide undercutting of flaps necessitated in the operation for thyroidectomy.

TECHNIQUE OF SUTURE

In an attempt to obtain more accurate approximation of the incised margins of the skin, fine arterial silk threaded on small straight needles of the milliner's type has been used (Fig. 8). This very fine suture material allows for accurate coaptation of the edges of the skin and its use is particularly valuable in the suture of wounds on the face. Inflammatory reaction about this very fine silk is much less than that about horsehair and stitches of this material leave no unsightly suture marks on the face. It is difficult to work with because of its fine caliber. When this suture material is applied with the on end mattress stitch ideal approximation of the cutaneous margins may be achieved.

The use of the crêpe lisse dressing as advocated by Halsted (8) is a valuable adjunct in the post operative care of the wound (Fig. 8). This dressing consists of a patterned piece of indestructible chifon. The material is firm, inelastic and smooth. Impregnated with collodion it is applied directly to the surface of the skin or, if the wound be not completely healed, over a layer of silver foil. In my opinion, this dressing is an invaluable aid in limiting the stress on a sutured wound when it is in the early stages of healing and before its maximal tensile strength has been reached.

SUMMARY

In order to promote ideal cutaneous healing of wounds and minimal cicatrization the following points in the technique and suture of clean surgical wounds are emphasized: the importance of placing the long axis of an incision parallel to Langer's lines of elasticity of the skin whenever possible, attention to the technique of incision so that the incision into the skin is not beveled, adequate undercutting of the skin and subcutaneous tissue flaps so that tension on the cutaneous line of suture is minimized, the use of silk ligatures and sutures, and the use of fine arterial silk for approximation of the edges of the skin in the suture of wounds of the face.

THE RATE OF EMPTYING OF THE HUMAN GALL BLADDER IN PREGNANCY

MAUDE M. GERDES, M D, and EDWARD A BOYDEN, Ph.D, Minneapolis, Minnesota

SINCE von Recklinghausen's notable discovery (1880-1887) that 90 per cent of women having gall stones have been gravid at least once and the subsequent finding by Courvoisier (1890) that three times as many women have gall stones as men, pregnancy has been considered to be one of the major factors in the development of cholelithiasis.¹ With the advent of the Graham-Cole method of cholecystography (1924), certain other corroboratory facts became available: first, it was noted that in pregnancy the gall bladder visualizes more slowly (D'Amato and Gmelin, 1927; Clauser, 1929) and remains visible longer (Kalk and Schoendube, 1926; Clauser, 1929); second, that gall-bladder bile, as recovered from the duodenum after injection of pituitrin, is more concentrated in pregnant women than in others (Kalk and Schoendube); and, third, that the gall-bladder sediment of such individuals frequently contains small cholesterin crystals (D'Amato and Gmelin). These facts all seemed to point to the existence of a gestational biliary stasis, but Boyden's statistical studies of 1927-1937—showing among other things that, after puberty, the gall bladder empties more rapidly in women than in men (a sex difference that persists even unto old age, Boyden and Grantham, 1936)—have made it imperative that a statistical analysis of the rate of emptying of this viscus be made in pregnancy.

The first direct proof that gestation retards evacuation of the gall bladder in mammals must be attributed to Mann and Higgins (1927). Working primarily with the thirteen-striped gopher, a small rodent that could be examined in large numbers as it becomes pregnant upon emerging from hibernation,

¹For general substantiation of these figures and for more recent statistics of the incidence of gall stones in men and women, see Schaefer (1932).

From the Departments of Obstetrics and Anatomy, University of Minnesota.

Aided by a grant from the medical research funds of the Graduate School.

these authors found that while the non-gravid animal regularly exhibited an empty gall bladder 4 hours after a meal of egg yolk and cream, only slight emptying was observed in the early stages of pregnancy and that from the middle of pregnancy to term there was no evidence of emptying at all. Scattered observations on other laboratory mammals seemed to support this view, but Whitaker and Emerson (1928)—after roentgenographing 5 cats, 3 of which showed only moderate emptying at 2 to 4 hours postcibum, and 2 human cases (1 of which had 20 gall stones)—concluded that "pregnancy in itself exerts no inhibitory effect upon the emptying of the gall bladder."

Curiously enough, the earlier cholecystographical studies of pregnant women seemed to support this view. Thus Levyn and Aaron (1928) having visualized the gall bladder intravenously in 10 of 17 primiparae who had no history of biliary tract disease, reported that in these 10 individuals the response to the Boyden meal was prompt and that adequate diminution or complete disappearance of the shadow occurred during the first, second, and third hours after the meal. Incidentally, the first picture was not taken until the end of the first hour postcibum.

The next study, by Fogelson (1929), yielded similar conclusions. Employing the oral method, this author was able to visualize the gall bladder in only 15 of 43 pregnant women, but he reported that in these 15 the biliary vesicle emptied within the normal period (which the author does not define) following a fat meal of 2 eggs, half a glass of cream, and butter fat.

According to Schaefer, Dellepiane (1929) reported that in the second trimester the gall bladder empties even faster than normal.

Close upon these initial studies came three articles that supported the contrary view. In each case the intravenous method was used. First, Naegeli reported that in 23 primigravidae (5 to 9 months pregnant—mostly

women about 20 years old without any history of hepatic or cholecystic disease) the emptying of the gall bladder was markedly delayed in 70 per cent of cases, i.e., 50 to 60 minutes after ingestion of 3 egg yolks, emptying had "hardly begun" and after 6 to 8 hours, the gall bladder was little more than half full.

More detailed figures were given in a subsequent study by Westphal and Gleichmann (1930-1931). Using Bronner's rough method of inspecting the size of gall bladder shadows after a meal of 3 egg yolks¹—his normal criterion being that by 1 to 1¼ hours the area (?) of the shadow be, at most, only 1/6 or 1/7 the size of the shadow at the beginning of the meal—these authors found that 6 of the 18 women tested were normal (most of the 18 being primigravidae and pregnant from 1 to 5 or 6 months). The other 12 showed marked delay in emptying. Details are given of each case, but the data are in such approximate and inconstant form that it is not possible to obtain mean values of the rate of emptying.

The last of this series, by Schaefer (1933), involved a study of 29 healthy women, mostly primiparae in the second half of pregnancy. Of the 27 cases in which the gall bladder was visualized, no change in the size of the gall bladder was said to be noticeable 15 minutes after a meal of 3 egg yolks. This statement, however, is not confirmed by tracings of cholecystograms from 4 of the author's 27 cases, for in 3 of the 4 (see his Figs. 6, 10, and 14) there is a distinct reduction in size at the end of the first 15 minutes. Further, it was stated that "often" the gall bladder exhibited a large residue at 6 hours, and that "all" gall bladders showed delayed emptying. Except for the few illustrations no data were given for the 27 cases.

Surveying these articles, which fall into two contradictory groups, it is apparent that with the possible exception of Westphal and Gleichmann's study, conclusions have been based upon general impressions. No article, for in-

stance, supplies enough detailed information to construct a mean curve of emptying for the group studied. Yet in the absence of this no one seems to have resorted to the device of testing the same individual twice, that is, during pregnancy and then afterward. Nor do any of these studies provide adequate normal controls. Even Bronner's method of estimating the size of the gall bladder shadow at 1¼ hours postcibum falls far short of furnishing an adequate idea of the rate of emptying since normal gall bladders, on the average, empty two thirds to three fourths of their contents within the first 40 minutes after a meal of egg yolk and some empty all but a minute residue in 15 to 20 minutes (Boyden, 1928, etc.). Nor is the method of guessing at the size of shadows satisfactory. As an illustration of this we have computed the relative volumes of the gall bladder in the 1 case in which Westphal and Gleichmann present cholecystograms. Where these authors say that at 35 minutes postcibum (their Fig. 3, cholecystogram 2) there has been "no emptying," we find a volume loss of 11.5 per cent, at 95 minutes postcibum (their Fig. 3, cholecystogram 3) where the gall bladder is said to be "half full," the volume loss is 71.3 per cent, and at 155 minutes postcibum (their Fig. 3, cholecystogram 4) where the shadow is said to be "the same," the volume loss is 74.9 per cent, even if the 35 minute reading be considered as unity, there is still a loss in volume at the 95 minute reading of 67.6 per cent. Finally, it is not clear at what point in the cycle retardation in emptying occurs, if such be the case.

Accordingly, it has seemed desirable to apply to this important problem the same quantitative methods that have made it possible to detect sex and age differences in the reaction of the gall bladder to a standard meal as well as its differing behavior in such closely allied diseases as peptic ulcer and carcinoma of the stomach.

MATERIAL AND METHODS

The material upon which this study is based consists of cholecystograms of 21 healthy pregnant women, 13 of them primigravidae, most of the latter coming from insti-

¹This test meal known in Germany and Italy as Bronner's is a modification of the original Boyden meal. It recognizes the sensitivity of a discovery in 1923 that egg yolk is the natural food most potent in emptying the mammalian gall bladder—an observation which was extended by him, in 1925, to include the human gall bladder. In its crude form however egg yolk is unpalatable also the cream is formed, the other component of the original meal is not necessarily rich. Therefore, for many years the writer has used 4 egg yolks mixed with an equal amount of milk (the whole seasoned with a pinch of sugar and a drop of vanilla) as being the most satisfactory for the purpose.

tutions for unmarried mothers. With one or two doubtful exceptions each case was selected on the basis of a negative biliary and gastrointestinal history.¹

In view of the difficulties encountered by other investigators in visualizing the gall bladder of gravid patients, it was deemed advisable to use the intravenous method. The dye selected for this purpose was sodium phenoltetraiodophthalein, since it was considered by the Mallinckrodt Company to be less toxic than its more familiar isomer and to be effective in smaller doses. For each patient 2.5 grams were dissolved in triply distilled water, filtered through fine paper, and sterilized for 15 minutes in a boiling water bath. The intravenous set-up was such as to permit substitution of saline for the dye whenever expedient. The solutions were kept warm in a water bath and run in by the gravity method, over a period of from 30 to 50 minutes. In each case the dye was preceded and followed by 100 to 200 cubic centimeters of saline in order to avoid any possibility of thrombosis. Several patients complained of some pain in the arm at the time the dye was introduced, but pain did not follow the course of the vein and seemed to be due to the position of the arm on the arm board. In general no untoward results followed the use of the intravenous method.

For the purposes of this test, patients were admitted about 4:30 p.m. and hospitalized for the next 20 hours. At 5 p.m. they were given a light supper of tea and toast. The dye was then administered about 7 p.m. Later in the evening or early in the morning a high flushing enema was given. Twelve hours after the dye a preliminary roentgenogram was taken with the patient lying face down and supported with pillows and sandbags, the lower abdomen being screened to protect ovaries and fetus. If the preliminary picture was satisfactory the patient was then given the modified Boyden meal² and x-ray films made at 0, 2, 4, 8, 12, 16, 20, 25, 30, 35, 40, and 45 minutes postcibum. Subsequently, the chang-

ing volumes of the gall bladder were computed from the cholecystograms after the graphic method described in previous studies (Boyden, 1928; Boyden and Fuller, 1934).

VISUALIZATION OF THE BILIARY VESICLE

Of 21 patients that received the dye intravenously, only 2 failed to exhibit a shadow of the gall bladder. One of them, (V.H., age 23, weight 179 pounds, pregnant 8 months) was a primigravida with an essentially negative gastro-intestinal history. The other (E. G., age 24, weight 176 pounds, pregnant 5½ months) had been gravid 3 times, the current pregnancy being characterized by much belching and heartburn. It is probably not without significance that in both cases the weight of the patient was excessively high. In a third patient (A. S., age 20, weight 116 pounds, a primigravida, pregnant 2 months) the gall bladder was visualized well enough to warrant further study but it failed to empty, probably because the egg yolk was vomited immediately. A fourth case—a 43-year old multigravida (I. D.), not included in the 21—had gall stones.

Although it is difficult to compare these findings with other reports in the literature, since complete information about individual cases is rarely given, our degree of success in visualizing patients approximates that of Schaefer's (1933) rather than any of the others listed in Table A; i.e., through the first 7 months it was not particularly difficult to visualize the gall bladder of healthy gravidæ. On the other hand, it was noted that in 4 of the 5 patients observed both antepartum and postpartum (Table IC) the intensity of the gall-bladder shadow was greatly improved 6 to 8 weeks after parturition. (In the fifth case, E. H., it was distinctly fainter.) It is evident, therefore, that pregnancy does affect the degree to which the gall bladder is visualized even if it does not prevent it entirely.³

¹Among others, Benda also advances the theory that pregnancy affects the absorptive function of the gall bladder or the excretory function of the liver, but since he fails to state whether he used the oral or the intravenous method, his data cannot be compared, statistically, either with ours or with Schaefer's material. According to his preliminary account, he examined 46 healthy gravidæ, 9 in the first half, and 37 in the second half of pregnancy. In the former group all gall bladders were visualized. In the latter group, the gall bladder could be seen in only 12 of 22 primigravidae and in only 5 of 15 multigravidae. Eighteen of the 37 were examined in the puerperium. In 3, the gall bladder remained unvisualized as in latter half of pregnancy, in the other 15 it was visualized regardless of whether it had appeared in latter half of pregnancy.

²The authors are greatly indebted to Dr. J. C. Litzenberg, Chief of the Division of Obstetrics and Gynecology, for the privilege of working with these patients and to Dr. Leo G. Kugler, head of the Department of Radiology, for the use of x-ray facilities.

³Four egg yolks mixed with an equal amount of milk (the whole seasoned with a pinch of sugar and a drop of vanilla).

RATE OF EMPTYING IN FIRST TRIMESTER

During the 2 years that these cases were being collected every attempt was made to obtain as many early pregnancies as possible, the only available source of supply being the Outpatient Prenatal Clinic of the University Hospitals. Unfortunately, most of those who came early in pregnancy were admitted for hyperemesis, pyelitis, or other complications that rendered the subject unfit for our purpose. Hence the material is limited to 5 healthy patients, 4 of them being multiparae. The individual curves of emptying are shown in Figure 1B. A glance at the last column of Table 1A shows that at 40 minutes after the standard meal, 4 of the 5 gall bladders had discharged from 66 to 78 per cent of their contents, as compared with the nulligravid mean of 73 per cent. The fifth case (A. R.) had been troubled with emesis and had vomited part of the meal between the 20 and the 30 minute pictures.¹ Even including this case the mean rate of evacuation for the first trimester is thus only a little slower than the rate for the nulligravid controls (Fig. 5A), the difference being not statistically significant.

EMPTYING OF THE GALL BLADDER IN THE SECOND AND THIRD TRIMESTERS OF PREGNANCY

For this period 13 healthy individuals were available, 10 of them being primigravidae.

¹We would interpret this cessation of emptying as being due to reverse peristalsis of the duodenum rather than solely, if at all, to a spasm of the sphincter of Oddi, because it has been shown in a cat that in spite of the fact that the gall bladder exerted enough pressure to inject the hepatic ducts, bile was unable to escape into the intestine while antiperistalsis of the duodenum was in progress (Boyden, 1926, Plate 1). Doubilet and Colp's recent statement that vomiting causes a spasm of the sphincter of Oddi (as determined by manometer studies made with the aid of T-tubes inserted into the human common duct) must therefore be accepted with reservation.

Detailed information about this group is given in Table 1B. The mean rate of emptying is indicated by the heaviest solid line in Figure 5A. When compared with the curve for nulligravid controls (lowest solid line in the same figure) there can be no doubt that in the second and third trimester, some factor in gestation has retarded the emptying of these gall bladders. Indeed, when submitted to statistical analysis it was found that there was not a single chance in a thousand that this difference could be due to random sampling. Even when the best 8 cases were averaged (for individual curves, see Fig. 1A) the mean curve showed retardation (asterisk, Fig. 5A). The most striking differences, however, appeared when the same individuals were tested during pregnancy and then afterward.

EMPTYING, 6 TO 9 WEEKS POSTPARTUM

It had been our intention to examine all pregnancy cases in the postpartum period also, but the unmarried status of most of these patients made it difficult to insure their return. In 5 cases, however, we were successful. As far as could be ascertained, these are the only instances in which the rate of emptying of the gall bladder during pregnancy has been checked by postpartum studies of the same individuals. Naegeli states that he did so once, but gives no further information.

When the two sets of curves of these primiparae are compared (Figs. 2 to 4), three significant observations can be made. First, the gall bladder exhibits marked recovery in its rate of emptying 6 to 8 weeks after parturition. At 40 minutes postcibum, for instance, the mean percentage of bile discharged by these 5 gall bladders is twice as great postpartum as during pregnancy (Fig. 5B). One would like to know exactly when this recovery takes place. We have not felt justified in disturbing the patient during the puerperium, but Schaefer (1933) reports a case in which pictures were made just before birth and continued from 2 to 4 hours after birth. The claim was made that immediately after birth emptying became normal, presumably because no shadow was observed at 120 minutes postcibum—perhaps it was diluted out by filling—but the cholecystograms made at 15

Fig 1 Individual curves of evacuation of gall bladder representing A cases of the second and third trimester that exhibited least retardation in emptying B 5 cases from the first trimester of pregnancy For original data see corresponding initials of patients in Table I Note that the slopes of the curves in the first few months (for the mean see next to lowest curve in Fig 5A) are steeper than those in the later months (for mean see asterisk Fig 5A) Cc bile volumes of bile in gall bladder as computed from cholecystograms 2, 4, 8 etc minutes after ingestion of standard meal (4 egg yolks and equal amount of milk flavored with sugar and vanilla) Curves designated by a fraction (viz $\frac{E.S.}{2}$) indicate that volumes have been plotted one half size

and 60 minutes postcibum, 1 e, between 2 and 3 hours after birth (his Figs 10 and 11) certainly show delayed emptying

The second observation is that in 3 of 5 cases the gall bladder is more distended during pregnancy than afterward (Figs 2A, 2B, and 4A) Potter (1936) found 75 per cent distended in a series of 390 cesarean sections at term

Third, retardation seems due primarily to an initial delay in emptying (compare mean curves of these 5 cases, Fig 5B), 1 e, to a fail

ure of the gall bladder to empty at the time when the passage of egg yolk into the duodenum should induce the greatest discharge of bile, namely during the first 20 minutes of a phase of emptying that averages only 32 minutes (Boyden, 1928)

Although we have studied only the first phase of emptying, which is always the most important, there is every reason to suppose that the lesser secondary phases would react the same way, the accumulated effect being then detectable at $1\frac{1}{2}$ hours postcibum, the

Fig 2 Individual curves showing evacuation of gall bladder at different times in same patient. Note that the gall bladder is more distended and that its rate of evacuation is more retarded during pregnancy than after parturition (Other legends as before)

time at which Westphal and Gleichmann made their observations

THE CAUSE OF DELAYED EMPTYING IN PREGNANCY

Among the numerous reasons advanced to account for ineffective discharge of bile in pregnancy is mechanical pressure exerted upon the biliary tract by the expanding uterus. But, Westphal and Gleichmann have pointed out that this does not become excessive until the late months of pregnancy. Since these authors found only partial emptying at $1\frac{1}{2}$ hours in patients gravid less than 6 months, they were probably justified in assuming that mechanical pressure was not the primary factor in this stasis of the gall bladder. Mann and Higgins also observed that when they placed small balls of paraffin inside the abdomen of gophers, to simulate the distention of pregnancy, the gall bladders of these animals emptied normally. It is instructive to note, however, that in the 4 patients in whom the gall bladder had been pushed into a horizontal position at the level of the tenth to twelfth ribs (Z C, A. G., L. G., and M. Pa., Table IB), the rate of emptying had been re-

Fig 3 Additional cases contrasting rate of emptying of gall bladder in antepartum and postpartum periods.

tarded. Position and pressure may, therefore, be contributory factors.

To test the matter, experimentally, we planned to study the rate of emptying in a series of myomatous women in whom tumors of the uterus were large enough to reproduce the mechanical pressures of the third trimester of pregnancy. Unfortunately we were able to obtain only 1 such uncomplicated case for study, but the evacuation of the gall bladder in this patient even exceeded the mean normal rate (Fig. 4B); for 81 per cent of its contents had been discharged by the 40 minute reading, notwithstanding the fact that

Fig 4 Individual curves contrasting effect of pregnancy with a purely mechanical distention of the abdomen caused by tumors of the uterus. For cholecystograms of Mrs. B., see Figure 6

Fig 5 Mean curves of evacuation of gall bladder of pregnant women reconstructed from data in Table I Vol % percentage of bile in gall bladder at a given time the volume at 2 minutes after the standard meal (when the gall bladder first goes into tonus) being reckoned as unity, 8, 1, etc minutes after standard meal

*Those 8 of the 13 gravid cases that showed 1st delay in emptying after a standard meal

†Those 5 of the 13 gravid cases that showed most delay in emptying

the tumor measured 20 by 14 by 8 centimeters (with a weight of 1200 grams) and was palpable three fingers above the umbilicus. From these figures it may be inferred that the uterus corresponded in size to that of a 7 months' pregnancy. Incidentally, the gall bladder of this patient contained a transverse congenital septum (Fig 6) not unlike that which occurs a little lower down on the gall bladder in cases of the folded fundus. But as pointed out in a previous study of the "Phrygian cap" (Boyd, 1935) such septa do not retard the rate of emptying any more than other congenital folds that occur normally in the neck and duct of the gall bladder.

It is apparent, then, that one must look for some deeper seated explanation of the biliary stasis of pregnancy, namely to a spastic condition of the sphincter of Oddi as first described for pregnant women by Westphal (1923).

This investigator observed that, when the gall bladders of non pregnant individuals were made to contract by injecting 30 cubic centimeters of a 5 per cent solution of peptone into the duodenum the amount of gall bladder bile being aspirated could be increased by intravenous injection of pilocarpine the

theory being that pilocarpine acted like a weak vagal stimulation in accelerating the contraction of the gall bladder musculature. When, however, the same procedure was tried on 10 women who were gravid 3 to 9 months (and 4 non gravidæ that were menstruating) the initial effect of pilocarpine was to inhibit the flow of bile for a period ranging from 3 to 20 minutes, following which there ensued a rush of dark bile. Westphal explained this initial inhibition of emptying by the assumption that in gestation the organism was already under increased vagal stimulation—as evidenced by such characteristic disorders of pregnancy as salivation, hyperemesis, and a tendency toward diarrhea—so that when pilocarpine was given it acted like a strong vagal stimulation (in animal experiments) and therefore produced at first a spasm of the sphincter of Oddi.

Undoubtedly Westphal has come very close to the probable explanation of this physiological aberration. At least he must be credited with having reproduced experimentally, by the use of peptone and pilocarpine, a comparable reaction to that which frequently occurs when egg yolk is ingested by pregnant women—namely, a prolonged initial delay in

the emptying of the gall bladder following what would normally be an excitatory stimulus¹

But whereas Westphal would attribute this longer pause of pregnancy to a "disharmony" of the autonomic nervous system, i.e., to a *hypertonische motilitäts-neurose* induced by the modified functions of the hypophysis, ovary or other endocrine organs—we would suggest that such a dyskinesia may be due equally well to the effect of hormones of pregnancy acting directly upon the musculature of the bile duct. It has long been known, for instance, that they inhibit the rhythmic contractions of the uterus. In thus preventing premature expulsion of the fetus they may produce imbalance in other muscular tubes. Especially is this true of the ureters, the musculature of which, incidentally, originates at the same fetal period as the sphincter of Oddi (Schwegler and Boyden). Apparently these changes affect the upper and lower portions differently, even as the latter have a differing innervation and are said to react differently to pituitrin. Thus the section above the pelvic brim undergoes an atonic dilation which Traut and McLane have recently shown to be characterized by progressive diminution of peristaltic activity from the third to the seventh month, after which the upper ureter begins to recover its activity. The muscle around the juxtavesical portion, however, undergoes an hypertrophy that results in constriction of the lower ureter (Hofbauer, 1928). Similarly the hormones of pregnancy may increase the tone of the sphincter of Oddi.²

Furthermore, there are other serious objections to applying to the human biliary tract, without qualification, Westphal's deductions from animal experimentation. In the first place we have seen no convincing evidence

¹Incidentally, Westphal frequently observed in non-gravid individuals a short delay in emptying, after pilocarpine, which he interpreted to be the initial response of the sphincter to stimulation. This probably corresponds to what one of us has described as the "two-minute pause" in the curve of emptying. It is not constant, but occurs so frequently as to be considered, perhaps, the typical reaction (see Fig. 3, Boyden, 1928). By the use of numerous cholecystograms it is possible to show that it usually appears not simultaneously with the ingestion of food but immediately after the gall bladder first goes into tonus. On the basis of McMaster and Elman's manometer studies on dogs (1926), this temporary interruption to emptying has been attributed to that increase in tone of the sphincter which commonly appears 2 minutes after ingestion of food.

²Some, indeed, might consider that there is a closer parallel between the response of the ureter and extrahepatic biliary tract to pregnancy, namely, that the gall bladder undergoes atony at the same time that the sphincter increases its tone. But we have seen no indication that the gall bladder of pregnancy is atonic.

Fig 6 Two cholecystograms from Case Mrs. Bu showing unusually placed congenital septum of a nature similar to that found in cases of folded fundus (the so called "Phrygian cap"). In spite of this anomaly and a mechanical distention of the abdomen equivalent to a 7 months' pregnancy, the gall bladder emptied normally (see text and curve in Fig. 4B). A, cholecystogram taken at 2 minutes postcibum, B, at 25 minutes postcibum

that emptying of the gall bladder in man (as contrasted with that in laboratory mammals) is under control of motor nerves. On the contrary there is justification for believing that such control is minimal, perhaps restricted merely to tonus changes; for distention of the human duodenum with air or water, or the smell of food, merely produces changes in volume of the gall bladder comparable to the first tonus changes after food, i.e., it results in taking up the slack in the wall but does not result in discharge of bile (Boyden, 1928).

Even more illuminating, however, are the experiments with faradic stimulation of the gut. In the cat, for instance, it is possible to inhibit the emptying of the gall bladder abruptly by tetanizing any portion of the intestinal tract (Birch and Boyden, 1930). In man, however, no such reflexes passing from the digestive tube to the gall bladder can be demonstrated. The gall bladder continues to empty, in response to the mere presence of egg yolk in the small intestine, in spite of severe colic-like pains emanating from induced spasms of the gastric or duodenal musculature (Boyden and Rigler, 1934).

Turning now to the sphincter of Oddi, the musculature of the human bile duct is strikingly different from the sphincter of the guinea pig and rabbit upon which Westphal has based his theory of biliary dyskinesia (Boyden, 1937). In the guinea pig, for instance, there is a musculature of the ampulla (Westphal's

Fig 5 Mean curves of evacuation of gall bladder of pregnant women reconstructed from data in Table I of % percentage of bile in gall bladder at a given time the volume at 2 minutes after the standard meal (when the gall bladder first goes into tonus) being reckoned as unity 3 8 12 etc minutes after standard meal

*Those 8 of the 13 gravid cases that showed least delay in emptying after a standard meal

**Those 5 of the 8 that were pre-rent normal

†Those 5 of the 13 gravid cases that showed most delay in emptying

the tumor measured 20 by 14 by 8 centimeters (with a weight of 1200 grams) and was palpable three fingers above the umbilicus. From these figures it may be inferred that the uterus corresponded in size to that of a 7 months' pregnancy. Incidentally, the gall bladder of this patient contained a transverse congenital septum (Fig 6) not unlike that which occurs a little lower down on the gall bladder in cases of the folded fundus. But as pointed out in a previous study of the "Phrygian cap" (Boyden, 1935) such septa do not retard the rate of emptying any more than other congenital folds that occur normally in the neck and duct of the gall bladder.

It is apparent, then, that one must look for some deeper seated explanation of the biliary stasis of pregnancy, namely to a spastic condition of the sphincter of Oddi as first described for pregnant women by Westphal (1923).

This investigator observed that, when the gall bladders of non pregnant individuals were made to contract by injecting 30 cubic centimeters of a 5 per cent solution of peptone into the duodenum, the amount of gall bladder bile being aspirated could be increased by intravenous injection of pilocarpine the

theory being that pilocarpine acted like a weak vagal stimulation in accelerating the contraction of the gall bladder musculature. When, however, the same procedure was tried on 10 women who were gravid 3 to 9 months (and 4 non gravidæ that were menstruating) the initial effect of pilocarpine was to inhibit the flow of bile for a period ranging from 3 to 20 minutes, following which there ensued a rush of dark bile. Westphal explained this initial inhibition of emptying by the assumption that in gestation the organism was already under increased vagal stimulation—as evidenced by such characteristic disorders of pregnancy as salivation, hyperemesis, and a tendency toward diarrhea—so that when pilocarpine was given it acted like a strong vagal stimulation (in animal experiments) and therefore produced at first a spasm of the sphincter of Oddi.

Undoubtedly Westphal has come very close to the probable explanation of this physiological aberration. At least, he must be credited with having reproduced experimentally, by the use of peptone and pilocarpine a comparable reaction to that which frequently occurs when egg yolk is ingested by pregnant women—namely, a prolonged initial delay in

mal nulligravid mean of approximately 73 per cent

Even more significant is the comparison of the rate of emptying in the same individual before and after parturition. The mean discharge at 40 minutes postcibum in 5 patients subjected to this test, was only 38 per cent during pregnancy as against 71 per cent, 6 to 8 weeks postpartum.

On the basis of Westphal's peptone and pilocarpine experiments with gravid women, this initial delay in the response to a motor meal is attributed to a hypertonic condition of the sphincter choledochus, i e., to a physiological dyskinesia reflecting the changed hormonal content of the organism in pregnancy. The evidence indicates that this delay is a lengthening of the normal "2-minute pause" that usually occurs immediately after the first rise in tonus of the gall-bladder wall following ingestion of food.

The resulting biliary stasis accounts for the distended gall bladders found at term in 75 per cent of Potter's large number of cesarean sections and for the thick, tarry contents of gall bladders at term which are characterized by a low bile-salt (and a high cholesterol) concentration that is comparable only to that found in vesicles with a damaged wall. In conclusion it is believed that the stasis of pregnancy sets the stage for the sequence of events which results in the greater incidence of gall stones among women that have borne children

"antrum") and a musculature of the duct of the ampulla (his "sphincter papillæ"). The peristaltic and expelling activity of the former he compares to the action of the pyloric portion of the stomach and the latter to the pyloric sphincter. In his pilocarpine experiments it is the former that first undergoes spasm and then expulsive activity. In man, on the contrary, there is no division of the muscle of the ampulla into proximal and distal parts. Indeed, the ampulla of Vater is rudimentary and the principal muscle of the duodenocholedochal junction is the sphincter choledochus which encloses the pre ampullary portion of the bile duct (Schwegler and Boyden, 1937). Due to the incompleteness of its longitudinal coat it cannot have any peristaltic function. Therefore Westphal's elaborate theory of antral and sphincteric segments, under respective control of parasympathetic and sympathetic nerves, breaks down when applied to man, notwithstanding Aschoff's gratuitous transference of the guinea pig terminology to the human sphincter in 1923. We do not mean to imply, however, that the human sphincter choledochus may not be under nervous control. Whether it is primarily regulated by hormones or the autonomic system, or both, has yet to be proved. Nevertheless, Westphal's notable demonstration that the initial interruption in the flow of the bile—our "two minute pause"—is greatly prolonged in pregnancy, points clearly to the existence of a gestational hypermotility of the sphincter choledochus.

THE RELATION OF PREGNANCY TO CHOLELITHIASIS

From this account it is clear that in the second and third trimesters of pregnancy the emptying of the gall bladder is markedly retarded during the first part of a phase of contraction that has been induced by the most potent food known to activate the gall bladder musculature. It inevitably follows from this that the biliary vesicle must accumulate stagnant bile during the period of gestation—the degree of stasis varying with the individual. Direct confirmation of this basic fact has recently been supplied by Potter (1936). First, he observed in 390 cesarean sections of preg-

nant women at term that approximately 75 per cent of these supposedly healthy individuals had a large globular, distended gall bladder. Second, an analysis of the contents of 58 of these biliary vesicles, withdrawn through a sterile needle at the time of section showed a raised cholesterol and a surprisingly low bile salt concentration—the latter comparable to that found only in a damaged biliary vesicle. The fact that none of these 58 gall bladders contained gall stones, however, does not militate against the possibility that in pregnancy the stage is set for the precipitation of cholesterol. While Neuman (1931) and Andrews et al (1932) have stressed the importance of the lowered bile salt content, Walsh (1933) reached the conclusion that altering the interrelationship of either the cholesterol, fatty substances, bile salts, or acids in the gall bladder alters the ability of the bile to hold cholesterol in an aqueous solution. The sequence of events might therefore be postulated as follows: Stasis resulting at first in an increasing concentration of bile salts with resultant damage to the gall bladder wall, alters the concentrating power of the mucosa and thereby changes the normal ratio of the constituents of the bile. If metabolic disturbance or infection be then superimposed upon stasis precipitation of stones might well follow.

SUMMARY

Detailed cholecystographic studies of 21 healthy gravid women following intravenous administration of iso iodeikon, have shown that while the gall bladder could be visualized in 18 of them (85 per cent), 4 of the 5 that were tested both antepartum and postpartum exhibited improved concentration of the dye 6 to 8 weeks after parturition. This finding points to a gestational alteration in the concentrating power of the gall bladder wall.

The rate of emptying of the gall bladder—as tested by the modified Boyden meal—is not significantly different from the normal rate during the first 3 months of pregnancy, but in the second and third trimesters there is a marked retardation in flow, the mean discharge in 13 cases being only 52 per cent (at 40 minutes postcibum) as against the nor-

KRUKENBERG TUMORS OF THE OVARY

Clinical and Pathological Study of 21 Cases

EMIL NOVAK, M D , F A C S , and LAMAN A GRAY, M D , Baltimore, Maryland

THE literature of Krukenberg tumors is not very extensive, especially when one considers that this tumor type has been recognized for more than 40 years. From time to time single cases, or small groups of cases, are recorded, and, since the tumor represents the most interesting type of metastatic ovarian cancer, it has received much attention in numerous papers dealing with secondary ovarian cancer, especially in the discussion of routes of dissemination from the primary focus to the ovaries. There are only a small number of American contributions to the literature of Krukenberg tumors, among which may be mentioned those of Major, Fallas, Jarcho, Hundley, and Andrews.

What is a Krukenberg tumor of the ovary? It is probable that the concepts of many gynecologists and pathologists on this point are rather vague. The term should be limited to the pathological entity described by Krukenberg in 1896, making allowance only for this author's misinterpretation of its real nature. The tumor was originally described as a sar-

coma ovarii mucocellulare carcinomatodes, but Krukenberg's description of its gross and microscopic pathological characteristics was otherwise quite accurate. The marked stromal reaction often seen, and in a minority of cases even suggesting sarcoma, together with the sparseness of the epithelial elements in many cases, led Krukenberg into the error of designating these tumors as sarcomas. This mistake was corrected by Schlagenhauser in 1902, and this author deserves the credit for establishing the epithelial origin of these growths, and for demonstrating the fact that in most instances they are secondary to carcinoma elsewhere, most often in the gastro-intestinal tract. This latter fact is responsible for the loose concept of some authors that all ovarian cancers secondary to gastro-intestinal cancer are Krukenberg tumors, which becomes apparent if one analyzes the cases in the literature. The definition must be much more circumscribed than this, and, if we are to continue this eponymic designation, should be limited only to those tumors, whether secondary or primary, which assume the characteristics first described by Krukenberg.

KRUKENBERG TUMORS OF THE OVARY

Clinical and Pathological Study of 21 Cases

EMIL NOVAK, M D , F.A.C.S., and LAMAN A. GRAY, M D., Baltimore, Maryland

THE literature of Krukenberg tumors is not very extensive, especially when one considers that this tumor type has been recognized for more than 40 years. From time to time single cases, or small groups of cases, are recorded, and, since the tumor represents the most interesting type of metastatic ovarian cancer, it has received much attention in numerous papers dealing with secondary ovarian cancer, especially in the discussion of routes of dissemination from the primary focus to the ovaries. There are only a small number of American contributions to the literature of Krukenberg tumors, among which may be mentioned those of Major, Fallas, Jarcho, Hundley, and Andrews.

What is a Krukenberg tumor of the ovary? It is probable that the concepts of many gynecologists and pathologists on this point are rather vague. The term should be limited to the pathological entity described by Krukenberg in 1896, making allowance only for this author's misinterpretation of its real nature. The tumor was originally described as a sar-

coma ovarii mucocellulare carcinomatodes, but Krukenberg's description of its gross and microscopic pathological characteristics was otherwise quite accurate. The marked stromal reaction often seen, and in a minority of cases even suggesting sarcoma, together with the sparseness of the epithelial elements in many cases, led Krukenberg into the error of designating these tumors as sarcomas. This mistake was corrected by Schlagenhauser in 1902, and this author deserves the credit for establishing the epithelial origin of these growths, and for demonstrating the fact that in most instances they are secondary to carcinoma elsewhere, most often in the gastro-intestinal tract. This latter fact is responsible for the loose concept of some authors that all ovarian cancers secondary to gastro-intestinal cancer are Krukenberg tumors, which becomes apparent if one analyzes the cases in the literature. The definition must be much more circumscribed than this, and, if we are to continue this eponymic designation, should be limited only to those tumors, whether secondary or primary, which assume the characteristics first described by Krukenberg.

From the Department of Gynecology, Johns Hopkins Medical School

Fig 4

Fig 4 Krukenberg tumor in Case 3 secondary to gastric cancer shown in Figure 5

What are the characteristics, gross and microscopic, which entitle a tumor to inclusion under this designation? Grossly such tumors are firm solid growths, usually of moderate size, almost always bilateral and retaining the general shape of the ovary (Fig 1). They are therefore rather kidney-shaped though not infrequently moderately

lobulated. External surface is smooth, with well developed firm capsule, with no tendency to become adherent to surrounding structures. On section, cut surface commonly of rather variegated appearance, some parts being quite firm others finely spongy, still others degenerated hemorrhagic or cystic, while areas of gelatinous appearance are common.

Fig 5

Fig 6

Fig 6 Photomicrograph showing transition from definitely adenocarcinomatous areas to those which have a

Fig 7

more typically Krukenberg appearance (Case 12)

Fig 7 High power of Figure 6 showing profusion of typical signet cells

This variegation in the gross appearance of the cut surface parallels and is due to corresponding differences in the microscopic structure in different parts of the tumor. The stroma in some parts may be firm and richly cellular, while in other areas it is edematous or genuinely myxomatous, as we shall presently discuss. In Krukenberg's original paper, and in most of those which have been published since then, stress has been laid upon the sarcoma-like character of the stroma, the feature which led Krukenberg into his error of classifying this tumor as sarcoma. We have not been impressed with the importance or frequency of this supposed sarcoma-like stromal reaction. Indeed, there is no case in our series in which the suspicion of sarcoma would seem justified by the stromal reaction to the epithelial growth.

The epithelial elements may occur as clusters of well marked acini, though always, in the true Krukenberg tumor, showing various degrees of mucoid epithelial change. Often this is so extreme that the epithelial cells are completely melted down, leaving only the shadows of the original gland framework. The mucoid material may break through the gland wall and permeate the surrounding stroma, so that differential staining may reveal mucin not only in the glands but also in the stroma. In still other parts of the

Fig 8 Gross appearance of unilateral Krukenberg tumor in Case 9. Inset shows primary annular carcinoma of colon.

tumor the original gland pattern may be entirely blotted out, though small clumps or strands of epithelial cells may be scattered here and there in the stromal fields (Figs 2, 3, 4, 5, 6).

The mucoid changes described explain the occurrence of usually large numbers of signet cells, in which the nucleus is flattened out against the cell wall by the accumulated secretion within the cell (Fig. 7). It is these

Fig 9 Microscopic appearance of primary adenocarcinoma of colon in Case 9.

Fig 13 Primary Krukenberg tumor of ovary (case of Dr C J Andrews Norfolk Virginia)

cells which have been most stressed in the microscopic diagnosis of these tumors, and which have suggested for them the very apt designation of carcinoma mucocellulare

The frequent persistence of adenocarcinomatous areas makes the classification of some cases rather difficult, for all gradations may be seen between tumors which must be designated simply as secondary adenocarcinoma, with more or less mucoid tendency to tumors in which all trace of acinous structure is lost. In other words, one finds transitional pictures which suggest the Krukenberg tumor may be only the end product of a mucoid adenocarcinoma which in the environment of the ovary assumes the features which we look upon as characteristic of the Krukenberg tumor. Our Case 9 is a good example of this group (Figs 8, 9, 10). In this patient the primary lesion was a mucoid carcinoma of the ascending colon. The ovarian tumor shows in many places a typical mucifying adenocarcinoma but in others the picture is entirely typical of the Krukenberg tumor both grossly and microscopically. Signet cells are seen in large numbers. We have felt justified in including this with several other cases of the same general type, in our series.

In still other cases the tendency to mucoid changes has been much less striking though present to some degree, and yet there has been the characteristic grouping of the epithelial elements in small clusters of tiny acini, or of epithelial cells, together with the characteristic stromal picture of Krukenberg tumors. Case 8 is an example of this type of tumor and this, together with several others of the same general character, we likewise believe should be included in our group of Krukenberg tumors (Figs 11 and 12).

These, then are the characteristics of the Krukenberg tumors in the proper sense of the term. From what has been said it would seem that this neoplastic type is brought about by the development of a primarily mucoid adenocarcinoma in the ovarian environment or by the acquisition of mucifying tendencies by metastatic tumors which at their original site give no indication of mucoid characteristics. Such a course is certainly not the invariable one pursued by gastro intestinal cancers metastasizing to the ovary for the great majority of such secondary growths develop as non mucoid carcinomas with the usual pattern of adenocarcinoma so that they can not properly be considered Krukenberg tumors.

Raiford found that only 11.8 per cent of gastric carcinomas show the presence of mucoïd material; for the small intestine the proportion is 14.3 per cent, the colon 30 per cent, and the rectum 24 per cent. This author distinguishes between "mucoïd carcinoma," a malignant growth rising from the mucin-forming elements, and "adenocarcinoma with mucoïd degeneration," characterized by the development of mucous deposits in a pre-existing adenocarcinoma. In the first group there would seem to be little doubt that the presence of the mucin is explainable as a result of hypersecretion of the tumor cells, and the same explanation would probably also apply to the second group, rather than that the mucoïd change represents a degenerative process, as some have suggested. In any event, our own material indicates that the Krukenberg tumor may be secondary to gastro-intestinal carcinoma of either of the two types named, and that, as a third possibility, the mucoïd changes may develop in the originally gastro-intestinal carcinoma only after its transplantation to the ovary.

When the primary gastro-intestinal tumor is of mucoïd type, it is natural to expect the ovarian metastasis to have the same characteristics. On the other hand, in a considerable number of reported cases, as well as in a number of our own, the primary tumor shows no suggestion of mucoïd change. Scirrhus carcinomas, and even linitis plastica, have constituted the primary foci in many cases in which, when transplanted to the ovary, the growth has developed highly mucoïd characteristics. After all, this need not be wondered at, for mucoïd changes are frequently noted in scattered areas of gastro-intestinal cancers of primarily and dominantly non-mucoïd type, not only of the gastro-intestinal tract but also of the gall bladder or breast, either of which may constitute the primary seat of the malignancy in Krukenberg tumors.

While the primarily epithelial histogenesis of the Krukenberg tumor has now been firmly established, there remain two moot questions which have been extensively discussed in the literature. The first of these deals with the route of dissemination of the

cancer from the primary seat to the ovary. There is very little direct evidence on this point, the opinions of authors being almost entirely based on their concepts of cancer dissemination in general, together with certain circumstantial evidence available on this particular problem. There are four possible routes to be considered: viz, (1) direct implantation on the ovarian surface of cancer cells, transported by the peritoneal fluid from the primary lesion into the pelvis; (2) lymphatic metastasis; (3) transportation of cancer cells by the blood stream; and (4) extension of cancer by direct continuity from an adherent intestinal cancer. The possibilities, therefore, are, with the exception of the first, the same as those which must be considered in the explanation of secondary carcinoma in other organs, though it is of interest to stress that direct implantation, considered to be of little numerical importance elsewhere, is credited by many authors as being by far the most important factor in the spread of gastro-intestinal cancer to the ovary. This explanation was first suggested by Bucher in 1893, and it has been adopted by many, probably the majority, of writers on this subject!

According to this view, carcinoma cells penetrate the wall of the stomach to the peritoneal surface and are then directed downward by the peristaltic movements of the intestines, this transportation being facilitated by the peritoneal fluid. In the pelvis they encounter the ovarian surfaces, which are presumably rendered peculiarly prone to implantation because of the portals created by ovulation. It will be seen that this interesting viewpoint embodies a number of premises which are unproved and practically unprovable. Some of them, moreover, lack the ring of plausibility.

Even very tiny lesions of the pylorus, not discoverable except on microscopic examination, have in some cases been associated with Krukenberg tumors of the ovary. It seems difficult to believe that in such cases cancer cells make their way to the serosa, and that a purposeful peristalsis carries them downward for ovarian implantation, without their planting themselves on the intestines, parie-

tal wall, or other structures which are known to be vulnerable to implantation in other forms of abdominal cancer. Moreover, if our ideas of ovulation are correct, the rupture of the follicle occurs through a very minute opening which is quite effectively sealed off in a short time, probably not over a few hours.

Again, if implantation were the usual route for this extension, would one not expect to find the growth primarily on the ovarian surface? As a matter of fact, Krukenberg tumors are characteristically enclosed in a dense, smooth capsule, with no sign of surface growth. All this reasoning is obviously theoretical, but it at least throws serious doubt upon the importance of the factor of implantation in the origin of Krukenberg tumors. Indeed, there is an increasing skepticism among pathologists as to the importance and frequency of cancer produced by this mechanism, though none, so far as I know, denies its possibility. On the other hand, the evidence indicates that such instances of "contact cancer" as are observed on the lips or on the vulvar labia can be much more adequately explained on the basis of lymphatic extension. The same statement applies to the cancer of the pleura which is not infrequently associated with cancer of the lung (McCallum).

After all, the route of cancer dissemination which the studies of many years have established as by far the most important one for carcinoma in general is that by way of the lymphatic system. It is upon this concept that the surgical treatment of cancer is in large part based. And here the evidence available in many special fields, like that of the breast or the uterus, is indubitable. It would seem that the burden of proof should be placed upon any explanation of the origin of Krukenberg tumors which departs from this underlying concept, especially when the attempt is made to apply it as a universal rule. It must be admitted that the direct evidence on the importance of the lymphatic route in the explanation of the origin of Krukenberg tumors is very meager, and that it is harder to secure than in other fields of cancer investigation. In another form of secondary ovarian cancer, that associated with uterine adenocarcinoma, the lymphatic

route is strongly suggested by the finding in grossly normal ovaries of small cancer nests in the lymphatics of the hilum, as shown in a previous paper by one of us (Novak).

The retroperitoneal glands, which are involved in most cases of pyloric and other forms of gastro intestinal cancer, are closely linked up with the lumbar glands, into which the ovarian lymphatics drain. Involvement of the lumbar glands in cases of Krukenberg tumor associated with pyloric cancer has been reported by Amann, but there has as yet been no very convincing demonstration of the transportation of cancer cells from the stomach, via the retroperitoneal and then the adjoining lumbar glands, to the ovarian lymphatics and then the ovary. This explanation obviously invokes the retrograde method of lymphatic dissemination, but the possibility of this has been well established and is accepted by all pathologists.

The fact that Krukenberg tumors are bilateral in nearly 90 per cent of the cases would suggest that the invading cancer cells reach the ovaries from a common distributing point having equal access to both organs, and the lumbar glands naturally suggest themselves as this distributing focus. The further fact that Krukenberg tumor, as well as most other types of ovarian cancer, is much more apt to involve the other ovary than any other pelvic or abdominal viscus makes this route seem the likely one.

With reference to the possibility of metastasis to the ovaries by way of the blood stream, there would seem to be no doubt, though here again the lack of real evidence makes it necessary to depend upon such evidence as is furnished by cancer characteristics in general. There are some, like Ribbert, who believe that blood stream transportation more often explains Krukenberg tumors than does lymphatic dissemination and it is possible that this is the correct view. Certainly this seems probable as regards the occasional cases following breast cancer, though even here one can not eliminate the possible importance of the lymphatic route.

Little need be said as to the few cases in which the ovarian involvement has been explainable by direct extension from a gastro

intestinal carcinoma, usually in the rectum or sigmoid, which has become adherent to the pelvic organs, so that direct extension into the ovaries was possible.

The second moot point regarding Krukenberg tumors is as to whether these neoplasms are invariably secondary or whether in the occasional case they may be primary. As to the secondary nature of the overwhelming majority there can be no question, and yet there is a small group of cases in the literature in which it is difficult to escape the conclusion that in rare instances a primary ovarian cancer may conform in all respects to the definition of a Krukenberg tumor. Evidence based on operative findings is clearly of little value, as a primary pyloric carcinoma may be so minute as to escape detection by palpation, and there is always a possibility that small undiscoverable tumors may be present in some other part of the gastro-intestinal tract or in the gall bladder. Even at autopsy, such small primary growths may be missed, and conclusions based on any but the most complete and careful autopsy records are not valid in the assumption of a primary origin of the ovarian tumor.

There are, however, several cases in the literature in which these specifications have apparently been fulfilled, and in which the evidence for a primary origin seems very strong. Among these may be included the cases of Schenk, Glockner, Sternberg, Frankl, Neumann, and Andrews. In most of these the evidence has consisted chiefly in the apparent elimination by postmortem studies or carcinomatous lesions elsewhere in the body. Microscopic examination of the stomach must be included, though this was not done in Schenk's case.

There is, however, another type of evidence which would seem to justify the conclusion that a Krukenberg tumor may be primary in the ovary. If such a tumor conforms pathologically and histologically in all respects to the Krukenberg variety, and if careful clinical study as well as examination at operation fail to reveal any other tumor elsewhere, the assumption of primary ovarian origin would seem justified if the patient remains free of symptoms for a term of years after the opera-

tion. So far as we know, no case of Krukenberg tumor of the common secondary type has been cured by the operation, death usually occurring within a comparatively short time, most often from the primary gastric lesion.

In at least two reported cases, those of Andrews and Frankl, the requirements just mentioned appear to have been met. Through the kindness of Dr. Andrews, we have had the opportunity of studying his tumor pathologically, and we agree with him that it is a typical Krukenberg growth, from both a gross and a microscopic standpoint. Dr. Andrews was good enough to have one of us (Novak) study this case clinically also. There was no evidence of any digestive disturbance, and a thorough study of the gastro-intestinal tract, including roentgenography, was negative. The operation was performed in 1933, and a recent letter from Dr. Andrews states that the patient is in excellent health, with no suggestion of recurrence 4 years after operation, and no evidence of carcinoma in any other organ. In such a case a skeptic would be justified in questioning the accuracy of the pathological diagnosis, but both the gross and microscopic findings in the original ovarian tumor, and their comparison with other typical Krukenberg tumors, would seem to offer no loop-hole in this regard.

A somewhat similar case has been reported by Frankl, whose patient was well $3\frac{1}{4}$ years after removal of Krukenberg tumors of both ovaries, with no gastro-intestinal symptoms and with negative x-ray findings. A third case may perhaps be added, that of Neumann, though this seems less convincing. In this case the ovarian tumor, described as of Krukenberg type, was only partially removable. Careful palpation of the liver, stomach, and intestine showed no evidence of tumor, and no gastro-intestinal symptoms developed after operation. Seven years later the patient returned with a solid tumor mass filling the pelvis, but still with no evidence of a gastro-intestinal lesion. Palliative treatment with x-ray was begun, and 9 years after operation the patient was still living and in comparatively good general health, with still no indication of gastro-intestinal cancer though the pelvic tumor was still present.

There are, after all, certain histogenetic possibilities in the explanation of primary ovarian cancers which may assume the Krukenberg type. Pseudomucinous epithelium is frequently encountered, especially in the common pseudomucinous cystadenoma. The generally accepted view as to the origin of pseudomucinous cystadenomas is that they represent teratomas in which an entodermic type of epithelium swamps out other elements, just as in thyroid tumors of the ovary (*struma ovarii*) the thyroid tissue blots out other teratomatous elements. There would seem to be no reason why the mucoid entodermic epithelium might not be the starting point of malignant tumors of a mucocellular type. That this variety of epithelium is of teratomatous origin is further indicated by the not infrequent occurrence in ovarian teratomas of small, often microscopic, cysts lined by epithelium identical with that seen in pseudomucinous cystadenomas.

Other possible sources of this type of epithelium are in association with Brenner tumors of the ovary, as Meyer has shown, and in the so called Walthard cell nests or islets from which such tumors are believed to be derived, though numerically these are far less important possibilities than the one mentioned.

While there is not the slightest doubt, therefore, that in the vast majority of cases the Krukenberg tumor is a secondary one we believe that the evidence for a primary origin in a very small group of cases is very convincing.

In view of the commonly secondary character of Krukenberg tumor, as well as of other types of ovarian cancer, examination of the ovaries should never be omitted at operation for pyloric or other gastro intestinal cancers in women. The gynecologist, on the other hand, should explore the stomach and other abdominal viscera before proceeding with operations for ovarian cancer. Not infrequently unwise or useless operations will thus be avoided, although in a number of reported cases both the primary tumor and the pelvic organs have been removed. In some of these the patients have survived for a considerable number of years, x ray treatment having in some been used after operation (Neumann).

Our own material consists of 21 cases of Krukenberg tumor which have passed through our laboratory during the past 25 years, although this number includes 3 cases which have been previously reported by Hundley, and also the case previously reported by Dr C J Andrews, of Norfolk, already alluded to in this paper. Most of these cases have occurred in our own clinic, but a number have come from outside sources. For their kindness in permitting us to include these we are indebted to Doctors Karl H Martzloff, of Portland, Oregon, E L Bowlus of Frederick, Maryland, I C Youmans, of Miami, Florida, F S Johns, of Richmond, Virginia, Clyde Hawley, of New York, and L E Daniels, of Detroit, Michigan.

The ages of our patients varied from 22 to 60 years, with an average of 42. Three patients were colored, the remainder, white. In 18 cases the tumor was bilateral, in 3, unilateral. In 6 cases the primary growth was demonstrated by operation or autopsy to be in the stomach, and in 5 others in the large intestine. In most of the others a possible primary tumor was either not sought for or not found. Ascites was noted in only 4 patients (1500 to 3500 cubic centimeters), it is possible, however, that it may have been present in others.

In all but 5 cases we have been able to secure more or less complete follow up data. Thirteen patients are known to have died, all within relatively short periods after the operation (6 weeks to 14 months). In 3 other patients death was obviously imminent when the patients were last seen, all of these showing definite metastases, chiefly abdominal. In 4 patients no follow up data are available. Autopsies were done in 4 patients who died in the hospital, 3 of these showing more or less extensive metastases (1 to the retroperitoneal and celiac glands, 1 to the peritoneum, 1 to the omentum and liver). In the remaining case there were no demonstrable metastases, the patient dying from the primary growth, an annular carcinoma in the ileocecal region. In only 1 case that of the presumably primary Krukenberg tumor of Dr Andrews, has the patient remained well (4 years after the operation was performed).

SUMMARY

This paper is based upon the clinical and pathological study of 21 cases of Krukenberg tumor of the ovary. The gross and microscopic characteristics of this tumor are described, emphasis being put on the fact that only a minority of ovarian cancers secondary to gastro-intestinal carcinoma conform to the proper concept of the Krukenberg type. While other routes of dissemination, such as transperitoneal implantation, may explain the ovarian tumor in some cases, we believe that the lymphatic route is far more frequently concerned in this, as in other forms of secondary ovarian cancer and of cancer in general.

There can be no question that in the overwhelming majority of cases Krukenberg tumors are secondary, usually to some form of gastro-intestinal carcinoma, but we believe there is very strong evidence for a primary origin in the occasional case. In at least 2, and possibly 3, reported cases (including the case of Andrews, discussed in this paper), the tumors were quite typical, there was no evidence at operation of a primary lesion elsewhere, none developed after operation, and the patients were still in good health several years after operation. It is difficult to explain such cases except on the assumption of a primary origin in the ovary.

The prognosis in the common secondary Krukenberg tumor is practically hopeless, as is indicated by the follow-up of our own cases. This is what one would expect in cancer which has already reached the stage of

lymphatic dissemination necessary for transport of cells from the stomach, intestine, or gall bladder to the ovaries, assuming that this is the usual method of spread.

A STUDY OF APPENDICITIS

An Analysis of 1,463 Consecutive Cases

EDWARD W. SPRAGUE, M.D., F.A.C.S., ROYAL A. SCHAAF, M.D., F.A.C.S.,
CLYMONT MACARTHUR, M.D., F.A.C.S., STUART Z. HAWKES, M.D., F.A.C.S.,
HAROLD HANTMAN, M.D., PAUL W. HALEY, M.D.,
Newark, New Jersey

THE high mortality of appendicitis continues to be one of the most serious problems before the profession today. Reference to statistics for the United States, the State of New Jersey, and the City of Newark, as shown in Table I, reveals a startlingly high mortality and the ratio of deaths per 100,000 population runs surprisingly close in these three geographical areas. It may also be noted that the death rate has not materially lowered in the years quoted.

This study is a record of a series of cases which have been managed by a uniform plan of procedure with minor variations. Presentation of such a series offers an opportunity for helpful analysis and criticism. It is also prepared for comparison. Such comparative studies will eventually evolve a fundamental solution to the problem of appendicitis.

This statistical survey includes all cases of appendicitis admitted to the C-2 Surgical Division of the Newark City Hospital during a 10-year period from 1927 to 1936, inclusive. There are 6 similar surgical divisions in this hospital. The hospital is a municipal institution for the care of the indigent sick. There are no private departments. The majority of the cases come from the low economic levels of society. Usually this group is slow in seeking medical advice and often tries self-medication first. This fact is one of the main reasons for the late admission of the patient to the hospital. All too often the disease has progressed far beyond the safety limit.

All cases in this series came to operation. As soon as the diagnosis of appendicitis was made, operation was advised. If the disease was acute, operation was performed immediately.

If the disease was not acute, the operation was performed on the next elective operating day. In case of doubt, in which an accurate diagnosis of appendicitis could not be made but in which there was presumptive evidence of acute appendicitis, operation was also done as an emergency. We believe that the error of operating in a case of doubtful diagnosis in which we find the appendix blameless is far less serious than failure to operate upon a patient later proved by necropsy or late operation to have had appendicitis.

TABLE I—STATISTICAL DATA

Location	Year	Population	Total no. deaths	Deaths from appendicitis	Ratio per 100,000 population	Ratio to total deaths

From the C-2 Surgical Division of the Newark City Hospital

Many of these operations have been done by the attending surgeons. On the other hand, virtually all the cases in which no complications were found were operated upon by the house surgeon on the service with the assistance or supervision of an attending surgeon. In the event of complications, the operation was completed by the attending surgeon. During this 10-year period more than 25 different house officers, in addition to the attending staff, have participated in this series.

TECHNIQUE

A definite plan of technique has been followed. Therefore, the results do not represent the work of an individual, but they do represent the success or failure of a definitely planned routine uniformly carried out with minor variations.

In the acute cases which are severely dehydrated saline and glucose solution is used intravenously before operation. Neither morphine nor atropine is given before operation in the serious cases. In the elective group small doses of one of the barbiturates are used.

The McBurney incision was used in all cases in which the diagnosis was reasonably certain. In doubtful cases, the right rectus or midline incision was made. In a few instances, more than one incision was necessary.

In the typical case, the appendix is delivered, the meso-appendix is clamped, cut, and ligated with catgut. The wound edges are protected with rubber dam and gauze sponges. The appendix base is crushed with a strong clamp and a catgut ligature is applied in the groove left by the clamp. A purse-string inverting suture is placed, the appendix is severed with the cautery, the stump is inverted and the pursestring tied. A row of Czerny-Lembert sutures covers this inverted area and includes the meso-appendix stump so that all raw surfaces and edges are buried. If the appendix cannot be delivered into the wound, or if we are dealing with a condition which no longer is confined to the appendix, long strips of gauze or sponges are used to protect the healthy peritoneum from the operative field. The appendix is removed in all cases, unless the disease has so fixed the tissues that attempts at removal seem too dangerous.

The appendix was not removed in 3 cases of this series which were complicated by general peritonitis because removal would necessitate excessive trauma. Usually we are able to invert the stump. In a few instances, we can only ligate and cauterize the stump, because the induration and friability of the tissues make it impossible or inadvisable to attempt inversion. Suction is used to remove the purulent material from the abdominal cavity and special attention is given to the pelvis. If there has been a perforation, or if gangrene or an abscess is present, a Penrose drain is placed in the pelvis and another in the right coloparietal space. The drains are brought out, as a rule, through a stab wound. The wound is now closed in layers. In a McBurney incision, when we have not encountered suppuration or gangrene, catgut closure is used throughout. If suppuration or gangrene is encountered, tension sutures of silkworm gut including the fascia together with catgut layer closure are used and small strips of rubber dam are placed down to the fascia or to the peritoneum. Tension sutures of silkworm gut, which include the fascia, are used in all other types of incisions.

If a history of a chill is obtained and examination has eliminated other causes, the possibility of thrombophlebitis is suspected and a high ligation of the meso-appendix is performed in an effort to prevent the development of an ascending pylephlebitis. If there is a history of one or more chills, or, in the late cases, if the patient has a fever of the remittent (spiking) type, the ileocolic vein should be ligated.

The question of the so called expectant treatment of the late fulminating cases has been considered. In our opinion peritonitis of a variable degree is present in all fulminating cases, and we feel unable to judge which of these cases may localize safely and which of them may become a spreading peritonitis. Furthermore, we believe that in these cases the prompt removal of the offending appendix with as little trauma as possible, followed by adequate drainage when indicated, gives the patient the best chance for recovery. In the late cases when a definite abscess has formed every attempt is made to drain the abscess.

TABLE II—CASES AND MORTALITY BY YEARS

Year	No cases	No deaths	Mortality per cent
1927	154	3	1.95
1928	112	7	6.30
1929	167	1	0.60
1930	130	4	3.00
1931	184	7	3.80
1932	154	3	1.90
1933	136	5	3.70
1934	131	4	3.06
1935	146	3	2.37
1936	124	4	3.22
Total	1463	40	2.73

cavity without contaminating the general peritoneal cavity. In other words, the surgeon should not convert a well localized abscess into a general infection of the peritoneum. In these cases adequate drainage can usually be obtained by placing the incision over the abscess and approaching the abscess cavity without entering the general peritoneal cavity. However, some of the cases with a definitely localized abscess cannot be managed in this manner. In such cases the abdomen is opened through a McBurney incision, and if free pus is not encountered and if a definite abscess is located, a second incision is made lateral or posterior to the abscess mass. Drainage is then secured by introducing a curved clamp through the second incision into the abscess cavity under the guidance of the hand in the peritoneal cavity. In this manner the peritoneum is not infected. When the abscess is inaccessible by this technique, it may be necessary to use iodoform gauze to wall off a passageway to the abscess through which the abscess may be subsequently opened without contamination of the peritoneal cavity.

Anesthesia. Open drop ether was always used for children and colored patients. Local and spinal anesthesia were used in a few cases in which their use was definitely indicated. Nitrous oxide-oxygen-ether was administered to all other patients.

Postoperative management. As soon as the patient regains consciousness, water is given freely by mouth. Small doses of morphine or pantopon are given for pain as needed. The

TABLE III—CLASSIFICATION OF CASES

Type	Cases	Deaths	Mortality percentage
Ruptured	123	31	25.4

Acute subacute chronic	1043	2	.19
Total	1463	40	2.73

indwelling Levin tube is used for vomiting after the first day. Gastric dilatation and intestinal distention are controlled by duodenal suction drainage through the Levin tube and by use of low glycerine enemas. With gastric dilatation the patient is also turned over on the abdomen, and the foot of the bed is elevated. Intravenous solution of 5 or 10 per cent glucose and normal saline are started at once on all serious cases and are continued until fluids are retained by mouth. If edema is noticed, salt is omitted in the intravenous solution. Transfusions are used when indicated as part of supportive treatment. In all cases in which intra abdominal drains are used, dependent drainage is favored by placing the patient in the right Sims' position. The bed remains flat. This position is maintained for 24 to 48 hours and is considered to be an important factor in the postoperative treatment. Removal of the intra abdominal drains is begun on the eighth or ninth day.

NUMBER OF CASES AND MORTALITY

During the 10 year period there were 1,463 cases of appendicitis with 40 deaths. The total mortality was 2.73 per cent. The mortality has varied from year to year as shown in Table II. We believe that this variation depends largely on the severity of the cases encountered during any given year.

CLASSIFICATION

We realize that clinical classification of appendicitis is difficult. Our grouping is a working classification and represents different stages in a disease process. This process may pass rapidly from the stage of an inflammation confined to the appendix to a spreading generalized peritonitis. Sufficient defensive reaction may hold the process to a limited area

TABLE IV.—INCIDENCE OF THE STAGES OF INFLAMMATION IN RELATION TO SEX AND RACE

	Male	Female	White	Colored
Ruptured	79	43	108	14
Gangrenous	93	36	118	11
Suppurative	108	61	154	15

Total	724	739	1342	121

within the protective walls made up of several inflamed tissues in the neighborhood, so that the infection becomes localized. Simple mechanics, such as dilatations or strictures of the lumen, also play a large part in the pathogenesis of appendicitis. Concretions are usually the localizing point of gangrene or perforation and a fecalith near the base often causes the so called obstructive type which becomes rapidly gangrenous throughout. Thus the structural deformities and the pathological changes of the appendix, the resistance of the individual, and the virulence of the infection are important factors in the rate of progress in the disease process. The same conditions may be found after a few hours illness in some cases that are found after days of illness in others.

Our classification as shown in Table III, while arbitrary, serves to arrange the cases into groups which have similar pathology. It also has a distinct meaning from the viewpoint of morbidity and mortality. This is a clinical classification and is made at the time of operation by the attending surgeon.

The four groups may be described as follows:

1. The ruptured group. The appendix is grossly ruptured and there is local or general peritonitis. A gross abscess may also be present.

2. The gangrenous group. The appendix is microscopically gangrenous with local or general peritonitis.

3. The suppurative group. The appendix is neither ruptured nor gangrenous but presents all degrees of suppuration with local or general peritonitis.

TABLE V.—STAGES OF INFLAMMATION IN RELATION TO DECADES

Decades	Groups 1, 2, 3				Group 4			
	Male		Female		Male		Female	
	W	C	W	C	W	C	W	C
1-10	39	3	21	2	34	14	30	7
10-20	81	8	59	0	137	20	305	16
20-30	66	9	18	1	125	10	130	8
30-40	37	6	13	0	63	2	50	1
40-50	18	0	6	0	28	1	21	1
50-60	8	0	6	2	6	1	5	0
60-70	5	0	2	0	2	0	1	0
70-80	0	0	1	0	1	0	0	0

Total	280		140		444		599	

4. The acute, subacute, and chronic group. This group includes all cases not in the three previous groups. Many of the acute cases presented marked evidence of acute inflammation but were included in this group when the process was confined to the appendix with no local peritonitis. The subacute and chronic cases presented milder types of inflammation and often revealed disturbances such as concretions, dilatations, strictures, and hypertrophy.

Frequently the surgeon will be uncertain in which group to place a given case. To avoid this difficulty, group 4 includes all but the fulminating cases.

A study of Table IV reveals that the incidence in the cases included in groups 1, 2, and 3 in the male exceeds that in the female by a ratio of approximately 2 to 1, while the incidence in the less active cases included in group 4 predominates in the female.

Tables VI, VII, and VIII, amplify important data contained in Tables IV and V.

In Table VI it will be noted that in the decade 1 to 10 years, there is lower incidence but higher mortality. The disease is rapidly progressive. In the decades 10 to 40 years, there is an increased rate of incidence with proportionately lowered mortality. In the age group 40 and over, there is lowered incidence with a raised mortality. Underlying degenerative, metabolic, and cardiovascular condi-

cavity without contaminating the general peritoneal cavity. In other words, the surgeon should not convert a well localized abscess into a general infection of the peritoneum. In these cases adequate drainage can usually be obtained by placing the incision over the abscess and approaching the abscess cavity without entering the general peritoneal cavity. However, some of the cases with a definitely localized abscess cannot be managed in this manner. In such cases the abdomen is opened through a McBurney incision, and if free pus is not encountered and if a definite abscess is located, a second incision is made lateral or posterior to the abscess mass. Drainage is then secured by introducing a curved clamp through the second incision into the abscess cavity under the guidance of the hand in the peritoneal cavity. In this manner the peritoneum is not infected. When the abscess is inaccessible by this technique, it may be necessary to use iodoform gauze to wall off a passageway to the abscess through which the abscess may be subsequently opened without contamination of the peritoneal cavity.

Anesthesia. Open drop ether was always used for children and colored patients. Local and spinal anesthesia were used in a few cases in which their use was definitely indicated. Nitrous oxide-oxygen ether was administered to all other patients.

Postoperative management. As soon as the patient regains consciousness, water is given freely by mouth. Small doses of morphine or pantopon are given for pain as needed. The

indwelling Levin tube is used for vomiting after the first day. Gastric dilatation and intestinal distention are controlled by duodenal suction drainage through the Levin tube and by use of low glycerine enemas. With gastric dilatation the patient is also turned over on the abdomen, and the foot of the bed is elevated. Intravenous solution of 5 or 10 per cent glucose and normal saline are started at once on all serious cases and are continued until fluids are retained by mouth. If edema is noticed, salt is omitted in the intravenous solution. Transfusions are used when indicated as part of supportive treatment. In all cases in which intra abdominal drains are used, dependent drainage is favored by placing the patient in the right Sims' position. The bed remains flat. This position is maintained for 24 to 48 hours and is considered to be an important factor in the postoperative treatment. Removal of the intra abdominal drains is begun on the eighth or ninth day.

NUMBER OF CASES AND MORTALITY

During the 10-year period there were 1,463 cases of appendicitis with 40 deaths. The total mortality was 2.73 per cent. The mortality has varied from year to year as shown in Table II. We believe that this variation depends largely on the severity of the cases encountered during any given year.

CLASSIFICATION

We realize that clinical classification of appendicitis is difficult. Our grouping is a working classification and represents different stages in a disease process. This process may pass rapidly from the stage of an inflammation confined to the appendix to a spreading generalized peritonitis. Sufficient defensive reaction may hold the process to a limited area

tions play an important part in increasing the mortality in these decades.

About 70 per cent of appendicitis occurs between the tenth and thirtieth years. Over 80 per cent occurs between the tenth and fortieth years. The youngest in this series was 1 year and the oldest 78 years.

The race incidence ratio as shown in Table VII is white to colored 11 to 1. The population of Newark, New Jersey is white, 415,000, colored 42,000, which is a ratio of 9.08 to 1. The disease incidence is definitely lower for the colored population while the mortality ratio is much higher.

The sex ratio of incidence as shown in Table VIII, male to female is as 1 is to 1.02. The total mortality percentage is higher in the male. However, in the fulminating cases the mortality is higher in the female (12 per cent).

Note: Pneumonia was the cause of the 2 deaths in the fourth group (acute, subacute and chronic).

than in the male (7.5 per cent). This computation is based on Table V and Table X.

HISTORY OF FATAL CASES

An accurate history of the onset of the disease was often difficult to obtain. Many of the patients were indefinite about the first symptoms. Of the 40 patients who died, 13 had been ill 1 day, 9, 2 days, 6, 3 days, 4 days, 1, 5 days, and 1, 6 days. Five patients had been ill over a period of 1 week, and 2 for 2 weeks. Two thirds or 25 cases were ill over 48 hours and one half of these were ill 4 days or longer. A cathartic had been taken before operation in only 5 cases. Our observation noted comparative safety if operation was performed within 18 hours after onset. After that time the danger rises in direct proportion to the time elapsing between the onset and operation.

In the 40 patients who died the McBurney incision was used in 17, right rectus in 18, right rectus and McBurney in 4, and midline in 1.

SUMMARY

1. A series of 1,463 consecutive cases of appendicitis is presented with a mortality of 2.73 per cent. All patients were operated upon.

2. The recording of a large series of cases following a uniform technique is of value.

THE RELATION OF CARTILAGE TO THE REPAIR OF BONE

J. DEWEY BISGARD, M.D., and J. MATTHEWS FARRIS, M.D., Omaha, Nebraska

SINCE much of the skeleton is chondral in origin and since much of the new bone in the repair of fractures and of defects from the loss of substance is laid down in preformed cartilage, there can be no question that under certain circumstances cartilage plays an essential and constructive rôle in ossification. In this rôle cartilage is embryonic in type.

As it matures to adult type, it becomes a somewhat fixed tissue and not only loses its osteogenic principle but becomes one of the least ossifiable of tissues and acts as a barrier to the repair of bone when it is interposed between fragments. Clinically, this is observed as a physiological principle, normally in the case of joints and pathologically in pseudoarthrosis.

These important differences between mature and immature cartilage are shown in the experimental observations which follow.

EXPERIMENTS

In 21 rabbits a segment of the shaft of each radius, approximately 20 millimeters long, was removed subperiosteally. In each animal the defect in the left radius was left empty and served as a control. Into the defects on the right side cartilage was transplanted and, according to the type of cartilage used, the experimental procedures diverge and fall into three groups.

Group I In 14 immature rabbits (1 to 3 months old) the radial defects on the right side were filled with autogenous transplants of costal cartilage. These grafts were sufficiently long to bridge the gaps between the fragments completely. Roentgenographical, gross, and microscopical examinations 12 weeks after operation showed: (1) union of fragments with partial or complete replacement of the resected segments in 12 of the 14 control defects (those left empty) and (2) the converse situation in the extremities in which the de-

fects were filled with costal cartilage. In this group not only was there failure of replacement of the resected segments but also failure of regeneration of sufficient bone to establish continuity between the fragments. In most instances there had been no replacement of bone whatever except at the ends of the fragments and very little or no evidence of osteogenic activity from the periosteum.

Histological examination showed that the cartilage had remained unchanged except where it contacted bone. Here, new bone arising from the fragments had fused with the cartilage by incrustation and superficial invasion.

Thus, the cartilage interposed between the fragments not only failed to ossify and to promote ossification but actually acted as a barrier to normal repair.

Incidental to the abnormal stress upon the ulna from the break in continuity of the radius there developed separation with displacement of the distal ulnar epiphysis in one-half of the extremities operated upon. In all of these, complete or nearly complete reduction took place spontaneously, but on the shaft of 7 of the ulnas there developed at the distal end where

Fig 1 Roentgenograms of both forefeet of rabbit 6, showing subperiosteal resection of a segment of the shaft of each radius. The defect in the left radius—at left—received no graft and served as a control. It became completely repaired. The defect in the right radius—at right—which was filled with an autogenous transplant of costal cartilage failed to repair. Note shadow of cartilaginous transplant.

From the Departments of Surgery and Physiology, University of Nebraska School of Medicine

Study of such a series will develop helpful leads whereby we may improve our management of appendicitis

3 The McBurney incision is our choice in acute appendicitis

4 The history of a chill in acute appendicitis, not explained by complicating disease, is significant of thrombophlebitis of the appendiceal vein. Under such circumstances high ligation of the meso appendix should be done and the ileocolic vein inspected and ligated if thrombosed

5 Dependent drainage is an important element in postoperative management of appendicitis

6 All procedures should be carried out with the idea of preventing peritoneal con-

tamination and spreading of local infection. Late cases with localized abscess should be drained without contamination of the general peritoneal cavity

7 The so called expectant treatment in late fulminating cases has not been practiced in this series

8 The medical profession must find ways and means better to inform the public of the great hazard of delaying operation

9 While we appreciate the fact that the human factors will make it impossible completely to prevent deaths in a large series of cases, nevertheless continued efforts to improve methods and an intensive education campaign for the laity will bring us surely, although slowly, toward that goal

THE RELATION OF CARTILAGE TO THE REPAIR OF BONE

J. DEWEY BISGARD, M D , and J. MATTHEWS FARRIS, M D., Omaha, Nebraska

SINCE much of the skeleton is chondral in origin and since much of the new bone in the repair of fractures and of defects from the loss of substance is laid down in preformed cartilage, there can be no question that under certain circumstances cartilage plays an essential and constructive rôle in ossification. In this rôle cartilage is embryonic in type.

As it matures to adult type, it becomes a somewhat fixed tissue and not only loses its osteogenic principle but becomes one of the least ossifiable of tissues and acts as a barrier to the repair of bone when it is interposed between fragments. Clinically, this is observed as a physiological principle, normally in the case of joints and pathologically in pseudoarthrosis.

These important differences between mature and immature cartilage are shown in the experimental observations which follow.

EXPERIMENTS

In 21 rabbits a segment of the shaft of each radius, approximately 20 millimeters long, was removed subperiosteally. In each animal the defect in the left radius was left empty and served as a control. Into the defects on the right side cartilage was transplanted and, according to the type of cartilage used, the experimental procedures diverge and fall into three groups.

Group I In 14 immature rabbits (1 to 3 months old) the radial defects on the right side were filled with autogenous transplants of costal cartilage. These grafts were sufficiently long to bridge the gaps between the fragments completely. Roentgenographical, gross, and microscopical examinations 12 weeks after operation showed: (1) union of fragments with partial or complete replacement of the resected segments in 12 of the 14 control defects (those left empty) and (2) the converse situation in the extremities in which the de-

fects were filled with costal cartilage. In this group not only was there failure of replacement of the resected segments but also failure of regeneration of sufficient bone to establish continuity between the fragments. In most instances there had been no replacement of bone whatever except at the ends of the fragments and very little or no evidence of osteogenic activity from the periosteum.

Histological examination showed that the cartilage had remained unchanged except where it contacted bone. Here, new bone arising from the fragments had fused with the cartilage by incrustation and superficial invasion.

Thus, the cartilage interposed between the fragments not only failed to ossify and to promote ossification but actually acted as a barrier to normal repair.

Incidental to the abnormal stress upon the ulna from the break in continuity of the radius there developed separation with displacement of the distal ulnar epiphysis in one-half of the extremities operated upon. In all of these, complete or nearly complete reduction took place spontaneously, but on the shaft of 7 of the ulnas there developed at the distal end where

Fig 3 The defect in the left radius (the control)—at left—received no graft and promptly filled with new bone

Fig 4

Into the defect of the right radius—at right—was placed fetal cartilage from the recipient's own fetus. Failure of repair resulted.

Fig 4 Bilateral radial defects. The left one—at left—was filled with an autogenous transplant of costal cartilage and failed to repair. The right one—at right—was bridged with an autogenous transplant of epiphyseal cartilage and became filled completely with new bone. It is to be noted that there is complete displacement and subsequent spontaneous replacement of the distal epiphysis of the left ulna.

separation occurred tumors composed of bone in 2 and of both cartilage and bone in 5, histologically osteomas and osteochondromas. In the distal fragment of the radius of 1 animal a giant cell tumor formed. A report of a study of these tumors was made in a previous publication.¹

Group II In this group 6 mature rabbits were used, and the defect in each right radius was filled with unossified but preosseous fetal cartilage and a defect on the opposite radius

used as a control. The fetuses from 2 to 3 weeks old were obtained by cesarean section in 2 instances and by induced premature labor in 1. The ribs, which at this stage of fetal life are almost entirely cartilaginous, were resected and divided into two equal parts, one portion being transplanted to the right radial defect of the maternal recipient and the other to a right radial defect in an unrelated animal. A comparison of the results 12 weeks after operation showed replacement of the resected segments of the radius by new bone in 4 of the 6 defects which received no transplants (the controls),

Burgard J D Experimental giant cell tumors and cartilaginous exostoses of bone. Arch Surg 1935 p 88

Fig 5 Serial roentgenograms of bilateral radial defects. Both repaired completely. The left one—3 at left—received no graft serving as a control, the right one—3 at right—was bridged with epiphyseal car-

tilage and absence of bone in all of those filled with fetal cartilage. The grafts in 2 of the 3 "fetus to mother transplantations" had been entirely absorbed, while those in the other group, the heterogeneous transplants, were undergoing absorption and were surrounded by granulation tissue and by round cells and foreign body giant cells and were encysted in fibrous tissue. New bone was present only at the resected ends of the fragments and at these sites in small amounts only.

Under the circumstances of this experiment, the osteogenic propensity of fetal cartilage cannot be judged. Its failure to give rise to new bone and its interference with normal repair are undoubtedly the result of tissue incompatibility, so often the fate of heterogeneous transplants. The transplants to unrelated animals not only were undergoing absorption but also had provoked considerable foreign body inflammatory reaction.

Group III In each of 4 young rabbits several small bits of cartilage¹ were removed from the epiphyseal cartilage plate of the distal end of the femur and were placed in the radial defects on the right side. In 3 animals the defect on the left side was left empty and in 1 it was

filled with autogenous costal cartilage. Within 1 week after operation all defects except the 4 containing costal cartilage had become filled with new bone. The defect containing costal cartilage had failed to repair. In all cases new bone had appeared earlier and definitely in larger quantities in the spaces to which epiphyseal cartilage had been transplanted, and sections through the newly formed bone revealed several small islands of cartilage, but whether this cartilage was that originally transplanted or was newly formed could not be determined. Slipping of the distal ulnar epiphyses occurred in 2 animals.

CONCLUSIONS

The results of these experiments confirm the clinical observations that, osteogenically, cartilage exists in two forms. In its embryonic form, characterized by the epiphyseal cartilage, it is very cellular and contains relatively little matrix and as such unquestionably plays an essential and constructive rôle in ossification. As a mature type of tissue with fewer cells and an abundance of matrix it not only loses its osteogenic propensity and becomes a somewhat fixed tissue and one of the least ossifiable but also acts as a barrier to repair of bone when interposed between fragments.

¹Since the epiphyseal cartilage plate is so small it is impossible to be sure that these tiny transplants were entirely free from minute spicules of bone.

AN INEXHAUSTIBLE SOURCE OF BLOOD FOR TRANSFUSION AND ITS PRESERVATION

Preliminary Report

J R GOODALL, M D, F A C S, F O ANDERSON, M D, G T ALTIMAS M D
and F L MacPHAIL, M D, Montreal, Quebec

THE teaching that, if the blood is left in the placenta, placental detachment from the uterine wall is hastened, has never had any scientific appeal to us. Consequently, it became a problem to be proved or disproved. So, at every birth, on our service, the clamp on the cut cord was released with the cord in a pendent position and the placenta was emptied so that the cord lay flaccid instead of quite turgid as was previously the case. The separation of the placenta was not appreciably changed either in elapsed time or complete-ness. A very important new factor was disclosed however: the blood pressure in the cord was great projecting the blood frequently 3 feet distant and the flow kept up a surprisingly long time. The thought occurred to us, why waste all this valuable material? So means were at once established to preserve this lost blood.

The first thing to be considered was a preservative. After much experimentation, it was found that the preservative proposed by the Moscow Institute of Haematology was the best available. A simple means of collecting the blood without contamination was established, and finally, considerable study was given to determining the best atmosphere for conserving the blood in its freshness. Blood grouping and Wassermann reactions received due consideration. The result of our work has been to provide an inexhaustible source of blood for transfusion and to preserve the blood at a minimum of cost and in a condition suitable for a transfusion medium for at least 60 days.

Technique. When the baby is born it is laid upon the mother's abdomen. The cord

is tied or clamped and wiped clean with a sponge moistened in 75 per cent alcohol. The cord is stripped free of blood for about 6 inches, by the left finger and thumb armed with a sponge. The cord is cut with a sterile scissors the severed end lowered to below the vulva. A special towel with a 2 inch hole in its middle is put over the hand, holding the cord in such a manner that the hand is opposite the hole. The towel is clamped to the operator's gown near the elbow with an Allis forceps. The end of the cord is passed through the aperture in the towel, and so placed that its end hangs in the funnel of the receptacle held by the nurse. Pressure on the cord is then released completely and the blood is collected. Pressure on the fundus by the nurse or assistant hastens the emptying of the placenta. When completed, the cord is clamped and the collecting has been accomplished. The towel described is used to prevent any contamination of the cord and receptacle by any fluid extraneous to that under collection. The process occupies about 3 minutes, and the average amount collected from each patient may vary from 100 to 150 cubic centimeters with an average of about 125 cubic centimeters. The technique used in collecting the blood is extremely simple and blood is always available when it is needed for transfusion.

Preservative. The preservative that has been found to be most suitable that proposed by the Moscow Institute of Haematology, consists of the following ingredients and their dilutions:

Sodium chloride	7.0 gm
Sodium citrate	5.0 gm
Potassium chloride	0.2 gm
Magnesium sulphate	0.004 gm
R ₁ -distilled water	1000.0 c cm

From the wards and Research Laboratory of St Mary's Hospital

This solution¹ is now put up in ampuls of 25 cubic centimeters which, when added to 100 cubic centimeters of distilled water, gives one the proper dilution, so that preservative and blood from each case is mixed in equal proportions, 125 cubic centimeters of preservative and, roughly, 125 cubic centimeters of fetal blood.

Preparation of receptacle A wide based glass flask of 300 cubic centimeters capacity and a glass funnel are thoroughly cleansed and rinsed several times with distilled water. One hundred cubic centimeters of distilled water and the contents of an ampul are put in each flask and corked with a stopper of absorbent cotton in gauze tied at the top. The flask and funnel are wrapped separately in a cloth and sterilized in the autoclave. When cooled they are ready for use. When blood is to be collected, the funnel is partially released from its cover and is handed aseptically to the surgeon. The flask covering is released from the top, so that when the nurse holds the flask by the base the cloth falls over her hand. The surgeon places the funnel in the flask, and the nurse holds these in position for receiving the blood. When the blood has been collected in the flask, a few drops from the end of the cord are taken in test tubes, one for grouping, the other for the Wassermann, if the mother's blood has not already been tested for the reaction. As all prospective mothers in our service have had Wassermann reaction tests made during their pregnancies, duplication of this test is not necessary. The flask and tubes are labeled with the patient's name and the date and are transferred to a refrigerator with a temperature between 33 and 38 degrees Fahrenheit. Temporary changes of this temperature do not affect the character of the blood.

The blood is ready for transfusion as soon as the grouping and reaction are completed. Groups 2 and 3 are kept in the upper shelves of the refrigerator. Groups 1 and 4 on the lower shelves, so that at a glance one can estimate the quantities in stock.

A clock thermometer on the top of the refrigerator indicates the temperature so

that it is not necessary to open the door. Defrosting should be done once a month, without removing the blood.

Conditions. There are certain conditions which become axiomatic as regards mother, child, and accidents of labor. Blood of the placenta will, of course, not be taken in cases of obvious transmissible disease in either mother or child. Eclampsia is not a contra-indication, however. Blood will not be taken in cases in which the membranes have ruptured for more than 48 hours before delivery, nor in cases of definite prematurity. In cases of marked asphyxia pallida, the amount of blood in the placenta is so small as to make it worthless.

Observations. Babies at full term have a fixed blood group. Consequently, the groups of donors of placental blood are relatively numerically the same as in the recipients. The supply in each group therefore will approximate the demand for each group. Major reactions are all that are necessary in cross-matching. Cultures of the preserved blood are unnecessary because, at the low temperature for preservation, contamination, if present, could not propagate, and consequently would be so attenuated as to be innocuous. When the placental blood settles, it frequently differentiates itself into three layers. The lowest is composed of red blood cells, the next is a thick buffy coat, and the third the supernatant clear fluid. Slight progressive hemolysis and consequent coloring of the supernatant fluid may occur after the first 15 days. This, even major degrees of hemolysis, is no barrier to a normal transfusion. Stirring or unnecessary movement of the blood is productive of slight hemolysis. The reason for the innocuousness of this hemolysis lies in the fact, that it would seem that the hemolysin is in infinitesimally small quantity and is inoperative in the recipient. Moreover, it is believed that the hemolysis is the result of the preservative upon fetal nucleated red blood cells, of which normal fetal blood contains quite a few, which possess greater fragility than adult red cells. This subject is under further study. Fetal blood, as regards cellular content, contains quantitatively approximately 7,000,000 red blood cells to the 4,500,000 of the adult.

¹This preparation is prepared by Ayerst, McKenna & Harrison, Montreal, under the name "Citro-seroid."

Its cellular strength, therefore, is about 150 per cent of that of the adult. Less fetal blood is therefore required. Every normal child at birth has therefore a well marked polycythemia. The reason for that is readily explained. In interchange of oxygen and carbon dioxide in the lungs between air and blood is at its optimum and is the equivalent of 100 per cent physiological effect. In the placenta, on the contrary, the interchange is between the maternal and fetal blood, and maximum interchange cannot exceed 50 per cent. Consequently, the fetal blood must have many more carriers, each with a degree of anoxemia, to extract a larger quota from the maternal fluids. This is self evident. If the fetus did not have this high degree of polycythemia, the fetus would be in a constant state of anoxemia. After birth, when the lungs come into operation, the excess of red blood cells becomes unnecessary, and the breaking down of these is the cause of many of the cases of hemolytic jaundice in the newborn. This explanation is advanced to meet the argument that in taking the blood from the placenta, one is depriving the newborn of its rightful due, and that one should wait until the contractions of the uterus have squeezed some of the placental blood into the fetal circulation.

Fetal blood contains from 20 to 35 per cent more coagulation power than that of adult blood. This, it is thought, is nature's provision to prevent exsanguination of the newborn in animals in which the cord is torn or bitten. This increase is gradually lost in the 10 days following birth. From the point of view of transfusion, this is an advantage in hemorrhagic cases, and it does not appear a contra indication of septic thrombophlebitis.

Preserved blood has many advantages over fresh blood. In the first place, food and other extraneous allergic reactions are eliminated. It is now a standing rule that, when possible, donors should not be used for some hours after ingestion of food. This is to obviate food allergic reactions. It is well known that certain individuals absorb a large quantity of

unsplit proteins during digestion and that these are capable of being neutralized by the allergins of that specific person, but the recipient may not be so fortunate, and, if not, an allergic reaction must follow. In preserved blood, autodigestion occurs and allergic reactions do not occur after 48 hours of preservation. A very amusing incident will accentuate this anomaly. A patient of ours was under transfusion from a donor. She suddenly developed hives. The transfusion was stopped and after the injection of adrenalin, the transfusion was resumed. When questioned upon her reactions to food, she stated that the only ingredient that she knew she could not take was gin. It always produced hives and she had not touched it for 15 years. When the donor was asked how much gin he had had that morning, in great alarm he answered, "I swear to heaven that I had only one drink, sir." He is still guessing how we knew.

In the many transfusions with fetal blood there has not been one untoward reaction, nor a single rise of temperature, even to a fraction of a degree, attributable to the transfusion. Before transfusion, the fetal blood should be heated in a basin of water and shaken before transmission. It should be filtered through two layers of sterile gauze. Two or more fetal bloods may be given simultaneously, if necessary, after separate matching.

A maternity section of a general hospital proportionate in size will give more than enough blood for the needs of the whole institution. Blood can be sent to other institutions in adequate thermos containers, if the group of the recipient is known.

The cost of installation varies with the custom duties of the different countries. In Canada, installation costs approximately 200 dollars. It would be much less in the United States. The installation soon becomes a source of revenue in that the charge to the private patients may be that of the usual donor's fee.

It is a safe, constant, efficient, and lucrative source of blood for transfusion.

OBSTETRIC ANESTHESIA

I. A Laboratory Method for Studying the Effects of Anesthetic and Analgesic Agents on Both the Uterus and Fetus

BARNET E. BONAR, M.D., and CHARLES M. BLUMENFELD, M.D., Salt Lake City, Utah

PUBLIC demand for relief of pain during childbirth has been responsible for a feverish search for a safe and effective obstetric anesthetic. Critical analysis of the voluminous and somewhat contradictory literature of the past 35 years reveals that an ideal anesthetic has not been found and that progress in this field has not been as great as might be hoped from the efforts extended. The question is raised also whether or not the use of obstetrical anesthesia may not play a part in maintaining the excessively high maternal and neonatal mortality rates during an era when other mortality rates have made a significant decline.

It is nearly impossible to obtain authentic information regarding the safety of the different anesthetics and analgesics in use because of unreliability of research methods and the interpretations made from them. Some of the faults in the methods of collecting and interpreting data are: lack of uniformity in the clinical standards used to judge the effects of drugs upon mother and child; use of an insufficient number of experimental subjects and controls; attempting to evaluate the effects of a drug while it is being used in combination with several, and insufficient use of precise laboratory methods. The outstanding need is for development of laboratory procedures which can be used preliminarily upon experimental animals before studies are made upon humans. Such methods may be used to confirm or refute some of the incomplete evidence which indicates that uterine contractions may be decreased and fetal asphyxia increased by these drugs. It is with this hope in mind that some of the methods that have

been used will be discussed and our experience with a recently developed laboratory method will be related.

METHODS OF PRECISION IN USE

Several methods of precision have been devised to determine the reaction of the uterine musculature to various anesthetics and analgesics. Unfortunately, studies of this nature have been too few to make it possible to arrive at convincing conclusions about these preparations. In fact, some of the methods have not been tried sufficiently entirely to satisfy some of the objections raised about them.

Excised uterine muscle test. By this laboratory procedure the effect of the various compounds on the uterus is determined by infusing a piece of excised uterine muscle with a solution of the test substance. The muscle is connected to a stylus which records the uterine contractions upon a revolving drum. While there are many objections to the use of this *in vitro* method, considerable information, at least of a preliminary nature, may be obtained before humans are subjected to the drug under consideration.

Internal hysterographic method. There is no need to describe at length the various procedures that have been devised to register graphically uterine contractions in parturients, for recently Dodek has done this in splendid fashion. Suffice it to say that internal hysterography was tried as early as 1872. Essentially the method is based upon the use of a rubber bag which is inserted under aseptic precautions either into the parturient human cervix or into the uterine cavity past the presenting fetal part. The amniotic sac should not be ruptured. The bag is attached to a rubber tube, and, after the two are filled with fluid, they are connected to a delicate tambour

or mercury manometer provided with a stylus which marks the uterine pressure variations upon a revolving recording drum. Recent studies based on this method have been made by Bourne and Burn, by Rucker, and by Kane and Roth in an endeavor to ascertain the effect of anesthetics and analgesics upon uterine contractions. So far an insufficient number of studies have been reported to arrive at very definite conclusions. Further more, internal hysterography has been criticized for several reasons. It subjects the patient to the dangers of intra uterine manipulation. Introduction of a bag may cause an abnormal response by the uterus thus providing a complicating factor in evaluating the effect of an anesthetic or analgesic upon uterine contractions. Finally, the method is sufficiently complicated to limit its generalized use by clinical investigators. Nevertheless, a great deal of valuable information might be obtained if the method were used more extensively.

External hysterographic method. As early as 1920 Rubsamen employed a method of recording uterine contractions from without the birth canal by registering changes of position of the abdominal wall. Mahon in 1930 reported using an external hysterographic method. In 1932 Dodek devised a simple method which was based on the fact that with each contraction of the uterus the antero-posterior diameter of the abdomen is increased in direct proportion to the intensity of the contraction. He fixed a plunger and diaphragm of a closed air system to the abdomen in the region of the umbilicus so that each contraction compressed the air which raised a stylus attached to a sensitive rubber tambour. The stylus recorded the contractions upon a revolving recording drum. The apparatus was fixed to the abdomen by tape. While the instrument is sensitive to uterine contractions it is relatively insensitive to ordinary abdominal movements of a minor character. For this reason as well as avoidance of hazards to the patient from intra uterine manipulations, the method should be a valuable adjunct to the study of uterine contractions under anesthesia or analgesia. Further more, observations can be carried out for

longer periods of time. So far few investigators have used external hysterography.

There is need for a laboratory procedure which may be used to determine the effects of the different anesthetics and analgesics upon the animal uterus before they are tried on humans. In the past year Rosenfeld and Snyder described a method that should be of a great deal of value in this respect. It has been used by them to ascertain the effect of anesthetics or analgesics upon the fetus *in utero* but we have found it useful in making observations of the effects of these substances on the uterine contractions as well. The method is described below.

METHOD OF ROSENFELD AND SNYDER

The abdominal and perineal regions of rabbits were anesthetized by transecting the lumbar spinal cord under local anesthesia. The animal was then partially immersed in a bath of Ringer's solution of body temperature. The abdominal wall was incised and the uterus was exposed. Various volatile anesthetics were administered through a cannula which had been inserted into the trachea of the mother, under local anesthesia. Solid analgesics were also administered in the usual way. The action of the different compounds upon the fetal respiratory movements were noted with the naked eye. Later motion picture studies were made with the assistance of Eastman (4).

We have employed this method with a few modifications. In some instances the cord was transected under ether anesthesia, but when this was done a day or two was permitted to elapse before the abdomen was opened, so that the effects of the anesthesia had worn off. By cutting the cord at a higher level the fifth and sixth thoracic vertebrae, the upper abdomen was anesthetized and the animal was not as restless. Most of the observations were made through the exposed but intact uterus. However in some cases the uterus was opened in order to study more closely the fetal respiratory movements through the transparent fetal membranes. In a few instances the outer chorionic layer was opened to eliminate some of the reflected light which at times prevented the enclosed

fetus from being clearly visible. Instead of using ordinary black and white film we have made our pictures with color film (kodachrome). Artificial illumination was furnished by four 750 watt photoflood mazda lamps so arranged that they could be adjusted in suitable positions. The camera was fixed in a frame at 2 feet from the object, and after the preliminary adjustments were made this stand could be brought into position quickly without requiring repeated focusing. This made it possible to standardize and simplify the photographic technique. The most satisfactory exposures were obtained with an aperture of F 2.8 using a 16 millimeter Eastman ciné-kodak with a F.19 lens and a speed of 16 frames per second. This photographic procedure made it possible to record movements that sometimes were overlooked when making direct observations and at the same time permitted permanent records to be made which could be reviewed from time to time. The use of color film made it easier to differentiate the various structures so that more accurate observation of details was possible.

FETAL RESPIRATORY MOVEMENTS

While mention has been made from time to time of respiratory-like movements in fetuses so little attention has been paid them that their existence still remains a doubtful matter to many. Thus, in the 1936 edition of *Williams' Obstetrics* Stander states that the conclusions of Ahlfeld regarding fetal respiratory movements have not been generally accepted and "we are still in doubt as to the significance of his observations." Preyer, in 1885 mentioned that Vesalius had observed such movements when the fetal circulation had been interrupted and that Winslow in 1787 observed rhythmic dilatation and contraction of the nasal orifices, expansion and contraction of the thoracic wall, and movement of the abdominal wall in the fetuses in the amniotic sac following exposure of the uterus. Beclard made similar observations in 1815. In spite of occasional references of this sort no particular notice was taken of the subject until Ahlfeld in 1905 reviewed two previous reports of his own and published graphic

records of rhythmic pulsations of the abdominal wall of pregnant women which seemed unrelated to maternal respirations or pulse. His views met with considerable opposition. In 1911 Reifferscheid confirmed these observations with graphic records and concluded movements of the fetal thorax resembling the respiratory act occurred *in utero* and that they were physiologic. In 1933 Klemperer failed to observe these movements consistently in anesthetized animals in which the uterus was exposed. Probably the reason for this is that anesthesia interferes with movements.

In 1935, Rosenfeld and Snyder noticed spontaneous fetal respiratory movements in the intact, but exposed, uterus of rabbits whose spinal cords had been transected. These were characterized by rhythmic excursions of the thorax and abdomen which, while shallower, resembled qualitatively the respiratory act in the newborn. Fetuses within the same uterine horn showed great variation in respiratory activity, some being quiescent while others exhibited these movements at varying rates up to sixty per minute. They thought that the movements were not initiated by the experimental procedure because they could be seen after careful observation of the unopened abdominal wall of unoperated upon pregnant animals.

By the use of ether, paraldehyde, sodium phenobarbital, and sodium-pentobarbital in amounts that did not impair the maternal respiration but caused light anesthesia, they found that the intra-uterine respiratory movements were either seriously depressed or inhibited completely. Eastman (5) who has been intensely interested in the work of Rosenfeld and Snyder mentions that they have also demonstrated these rhythmic intra-uterine movements in the cat, guinea pig, and monkey. After carefully reviewing the scanty literature on the subject and after making personal observations which will be related below, we have come to the conclusions that intra-uterine respiratory movements of the fetus occur, that they are physiologic, and that they are not initiated by asphyxial changes in the fetal blood nor by stimulation as a result of handling.

AUTHORS' OBSERVATIONS

Using the method described herein, observations were made on 10 rabbits, 5 dogs, and 7 rats, and color motion pictures were taken. The following observations were made.

1 *Fetal respiratory movements* Through the intact uterus periodic rhythmic excursions of the fetal thorax and abdomen were observed. There seemed to be no synchronous action between the different fetuses, some remaining quiescent while others were active. These movements seemed to be of about equal intensity or amplitude but not of the same rate. Frequently all were inactive for a short time. One rabbit (No. 7) was observed for over $1\frac{1}{2}$ hours and during this time, save for a period of 2 minutes, one of the fetuses continued to manifest these rhythmic movements uninterruptedly. Sometimes as many as 3 fetuses showed respiratory activity. These movements were affected by several factors. In premature fetuses the respiratory activity was not as great as in full term animals. The movements often stopped when the fetus kicked and squirmed about. During intense uterine contractions the respiratory movements ceased or were at least considerably reduced or obscured. Frequently the rate was increased after the uterine contraction had subsided. The thoracic abdominal movements did not seem to be disturbed when the uterus was opened and the amniotic sac exposed unless, as happened several times, the placenta became detached. Viewed through the transparent fetal membranes the movements simulated very closely the respiratory act in newly born animals. First, the chest was raised upward and outward suddenly while the abdomen retracted. Then the chest retracted and the abdomen expanded, but this movement was not as rapid as the initial one. During this act the ribs moved upward and downward. The respiratory like movements, in dogs especially, were accompanied in most instances by alternate opening and closing of the mouth. In rat fetuses this was not as noticeable. We observed two distinct types of movements. The first was a rhythmic and regular act of relatively uniform amplitude unaccompanied by any other fetal

activity. The second resembled an asphyxial gasp in which the mouth was opened wide if the excursion was violent. Movements of this sort usually were not rhythmic, and preceded or occasionally were accompanied by active limb movements. The fetus appeared to be struggling for breath. In rats greater variation of rate and rhythm was seen. At times the movements were so rapid that the chest did not have time to relax completely between excursions. This was followed by a pause simulating closely the apnea following a series of rapid respirations in delivered animals. When the umbilical cord was clamped, increased fetal and respiratory activity was usually, but not always observed. With rat fetuses this was not as likely to happen. The width the mouth was opened depended upon the intensity of the thoracic excursion.

The respiratory movements were stopped within 5 minutes by light ether anesthesia at which time the usual fetal response to tactile stimulation was absent. At the beginning of the anesthesia the rate was often increased. Within 5 to 10 minutes after withdrawal of the anesthetic, occasional excursions of the thorax were seen and by 15 to 20 minutes they had become regular again but the rate was slower.

Sodium iso amyl ethyl barbiturate (sodium amtal) in doses sufficient to produce analgesia and drowsiness was found to affect the fetal respiratory movements. At first the rate was increased somewhat but within 10 minutes it was reduced and the movements were not as uniform in intensity. By 15 minutes they were still more shallow about every fourth one being of normal strength. Rhythmicity, however, continued. In one instance the movements ceased at 42 minutes for 2 minutes and after their reappearance the rate was slowed one half or more with about every sixth one stronger than the rest. In this rabbit fetus the movements continued for over $1\frac{1}{2}$ hours and were still going when the experiment was stopped.

The rate varied greatly in different fetuses, in different species of animals, and in fetuses of varying maturity. In general the rate in dogs was less than in rabbits or rats and in premature animals it was slower than in ones

at term. Variations from 4 to 90 a minute were observed but in the few animals studied there seemed to be no rate characteristic for the species. Ether rapidly reduced the rate finally causing complete cessation. Sodium amytal slowed it gradually. For instance, rates of 30 to 40 per minute were reduced to 10 to 15 and finally cessation of respiration occurred.

2. *Uterine contractions.* In the reports of Rosenfeld and Snyder and of Eastman no particular mention was made of uterine contractions. We noted that in some animals operated upon at term uterine contractions were so vigorous that they interfered with our observations and photography of the fetal respiratory movements. In 2 rabbits labor began during the course of the experiment. Uterine movements were less bothersome in animals operated upon a few days before term and in ones that had been given theelin injections to prolong the gestation period. Contractions were seen very distinctly which gradually moved toward the vagina. The portion immediately behind the wave of contraction dilated or expanded. When ether was administered to the mother, contractions became less frequent and intense, finally disappearing entirely. Sodium amytal reduced the frequency and intensity of uterine contractions.

Since our investigations were initiated primarily in order to study the fetal respiratory movements, observation of uterine activity was more or less secondary. However, sufficient information was obtained to make us feel that this method could be used satisfactorily to study simultaneously the effects of anesthetics and analgesics upon uterine contractions as well as fetal respiratory activity. While the activity of the uterus during actual labor would not be recorded, always valuable information, nevertheless, would be obtained. Furthermore, in some instances, as happened in some of our rabbits, labor might begin during the course of an experiment in which instance the effects of anesthetics and analgesics upon the parturient uterus could be studied. Finally, it would be possible to induce labor in order that such observations might be made.

EVALUATION OF STUDY

The method described offers several advantages. Primarily it is of value because it permits tests to be made upon laboratory animals rather than humans. Taking motion pictures makes it possible to preserve the observations for reference. Thus, experiments may be reviewed, checked, and detailed studies made of the character and quality of the movements. Also demonstrations may be made before medical groups. The chief value of the method, however, lies in the fact that it is possible not only to determine the effect of various preparations upon the uterus but also upon the fetus *in utero*.

Certain disadvantages have been found. The method is subject to personal error in that it depends entirely upon observations made with the eye. Because of this it is difficult to continue the studies for extended periods and the use of moving pictures for a protracted time is expensive. Furthermore, it is extremely hard to time the movements accurately.

Objections may be raised about the manner of preparing the animal for the experiment. Thus, doubt may be expressed about the occurrence of fetal movements in unoperated upon animals. Rhythmic movements of this nature have been observed in unoperated upon laboratory animals and humans (Ahlfeld, Rosenfeld and Snyder) and graphic records of these movements through the unopened abdominal wall have been published (Ahlfeld, Reifferscheid). In the face of this, surely such factors as mechanical stimulation by operative manipulations, immersing solutions, temperature variations due to inadvertent exposure of the uterus to the air and heat of artificial illumination, cannot be incriminated very well. As far as the solutions are concerned they are generally considered physiologic enough to be suitable for experimental and clinical purposes. The solutions are kept at body temperature and the heat caused by illumination can be controlled easily. Drying can be prevented by total submersion and, in fact, there is less glare when this is done. Interference with the uterine blood supply can be eliminated by care in setting up the preparation. Another criticism is that the release of intra-

abdominal pressure upon the uterus by opening the peritoneal cavity may affect uterine contractions or fetal respiratory movements. Since the action would be one of retardation rather than stimulation we do not consider this factor of much importance.

Perhaps the most pertinent criticism pertains to transection of the spinal cord. It is possible that this may interfere with the innervation of the uterus and in turn with normal uterine contractions but one cannot conceive of any particular direct effect upon the fetus as a result of this act. The uterus is thought to possess an inherent capacity for rhythmic contraction. Under normal conditions uterine activity is governed by both motor and inhibitory nervous influences which probably are of reflex or central nervous origin. When the cord is transected the only effect to be expected would be removal of the central nervous influences. How great this is one cannot state definitely. The effects caused by transection of the cord and spinal anesthesia are similar in many respects. Several observers have studied this problem in relation to the uterine contractions during labor. Some of their conclusions have been somewhat contradictory. Bourne and Burn, after reviewing the subject carefully and making hystero-graphic studies, concluded that while under spinal anesthesia "the rhythm of the uterine contractions was not perceptibly altered there was a maintained rise of pressure in between each uterine contraction." In other words uterine tone was increased. Since the rate and rhythm of the contractions are not interfered with it appears that cord transection may be used satisfactorily in testing the stimulating or depressing effect of anesthetics and analgesics on uterine contractions, especially after determining what constitutes normal for the cord animal.

In spite of certain objections it is our opinion that this method is of distinct value in testing the action of the various agents upon fetus and possibly uterus. Studies along these lines should be continued and the method used until a better one can be devised. It is hoped that an instrument can be developed to record graphically the volume changes of the uterine musculature and the fetus *in utero*

in animals prepared in this manner. Perhaps an instrument devised by Fenning to record graphically small changes of volume can be adapted to this particular purpose. We intend to carry out investigations to determine if this is possible.

SUMMARY

There is need for greater use of precise methods to determine the effect of anesthetics and analgesics on uterine contractions and on the fetus. As far as the uterus is concerned hystero-graphy is the method of choice at present. Especially is this true of external hystero-graphy since it is reasonably accurate, simpler, safer for the patient, and less subject to criticism. A procedure recently described by Rosenfeld and Snyder offers great possibilities in studying the effects of anesthetics and analgesics upon the fetus. Experiences with this method are related and the observations of Rosenfeld and Snyder regarding the existence of apparently physiologic intra uterine respiratory movements which are depressed or stopped by some of the anesthetics and analgesics are confirmed. There is evidence that this method may be of value in studying the effects of these agents upon uterine contractions also. Direct and color motion picture observations upon animals anesthetized by cord transection are reported and the advantages and disadvantages of the method are discussed. In order to obtain more accurate data there is need for an instrument which will record these movements graphically. It is possible that this may be accomplished in the near future by using an instrument recently devised by Fenning to record graphically small changes of volume. Further studies along these lines are being pursued.

INGUINAL HERNIA

I The Anatomy of the Region

BARRY J. ANSON, Ph D, and CHESTER B. McVAY, BA Chicago Illinois

OVER a period of several years the authors gathered data on what were at first regarded as unusual types of abdominal musculature. As records accumulated the incidence of the "unusual" cases became high, it was soon learned that they were not exceptional, but merely different from the arrangements conventionally described and figured. A study was then begun on the abdominal layering of consecutive specimens, 123 specimens have been studied to date, a number which seemingly includes all types of musculoaponeurotic layers and gives a reliable concept of the incidence of each. In the following account we shall present those features of the anatomy which are regarded as surgically important. In this selection the writers were dependent in part on the judgment of Dr. Leo M. Zimmerman, whose presentation of the principles of hernial repair, appearing in a separate article in this journal, is correlated with the anatomical discussion.

MATERIALS AND METHOD

The descriptions are based upon records obtained from the dissection of 125 consecutive specimens (250 inguinohypogastric regions).¹ The illustrations represent the anatomy of 3 selected cases. Specimen A represents the commonest type of internal oblique muscle. Specimen B represents a less common arrangement in which the inguinal parietes are almost entirely aponeurotic, upon the opposite side of this specimen Dr. Zimmerman carried out the operation which is illustrated in his article. Specimen C is dissected to demon-

strate the relation of the 3 aponeuroses to each other and to the rectus muscle. Figures 6 and 7 are diagrammatic composites based upon our records of the internal oblique and transverse abdominis muscles.²

DESCRIPTION OF SPECIMENS ILLUSTRATED

Specimen	Race	Age-Years	Height inches	Weight pounds	File number
A	White	57	68	150	1
B	White	53	65	190	2-3-4
C	Negro	61	68	150	5

EXTERNAL OBLIQUE MUSCLE

In the inguinohypogastric region the external oblique muscle is entirely aponeurotic. It is usually considered as forming the major portion of the rectus sheath in this region yet actually contributes relatively little to that structure (Fig. 5), it is readily separable from the aponeurosis of the internal oblique along a semilunar line which lies progressively nearer the linea alba as the pubic crest is approached (Fig. 1), the two lines frequently coinciding just above the pubic symphysis.

The aponeurosis of the external oblique is regularly described as having a pubic insertion additive to the two crura of the subcutaneous inguinal ring, this extra band, the reflected inguinal ligament is composed of a group of fibers derived from the deep surface of the aponeurosis, which do not terminate at the middle line of the body in the substance of the linea alba but, crossing to the opposite side, insert into the pubic crest and tubercle. Actually, the reflected ligament rarely occurs, it was present bilaterally in less than 1 per cent of the subjects unilaterally in 3 per cent. When present it overlies the strong rectus muscle and therefore could be of no service in preventing direct inguinal herniation.

¹Permanent records were obtained of the extent and character of the inguinal layers in each subject by outlining upon glass with wax pencil and then transferring to tracing paper all features of interest. Details of structure were then added free hand to the sketch while a written description was being prepared by an assistant. Supervised student dissections were usually satisfactory for study and record but whenever a dissection offered difficulties or presented apparently novel features, it was completed by the authors.

Contribution No. 259 from the Anatomical Laboratory of Northwestern University Medical School

²Another article by the present authors on the subject of a general anatomy will appear in the Anat. Record 1938 70 No. 4

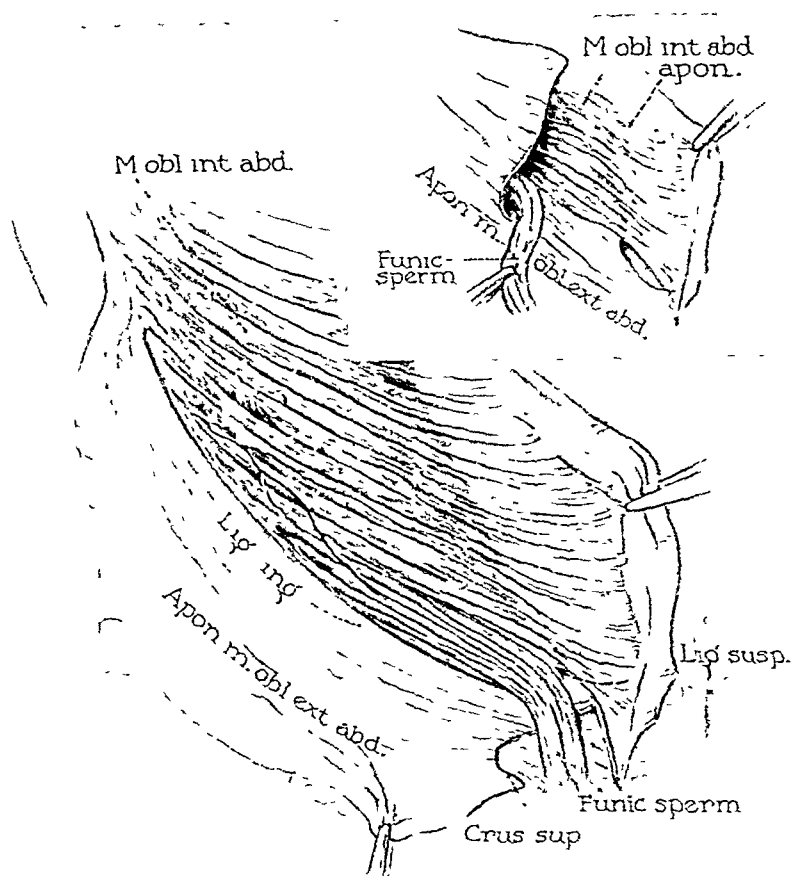

Fig 1 Specimen A The usual type of internal oblique muscle and aponeurosis (Fig. 6), the stratum is exposed by reflection of the external oblique. An "aponeurotic inguinal falx" is artificially produced by dislodging the cord and its cremasteric investment from the sulcus in the internal oblique muscle, a cleft (at arrow) is thereby produced, which sets off a falciform band from the cremasteric fibers. a, insert, Anatomical demonstration of the use of an intumed flap of the external oblique aponeurosis to strengthen the region of direct inguinal hernia (see following article)

INTERNAL OBLIQUE MUSCLE

The internal oblique is almost invariably described and figured as a layer which is entirely muscular in its inguinal portion, aponeurotic only in the hypogastric region, where it contributes to the formation of the rectus sheath. It is, according to our observations, generally true that the stratum is chiefly muscular, the latter two-thirds being made up of muscle fibers, the medial one-third of aponeurosis (measured to the lateral border of the rectus muscle). But there are notable exceptions: the muscle may be short in either transverse (Fig. 2) or vertical direction (Fig. 6), al-

though, in most instances (97 per cent) it extends inferiorly to the spermatic cord.

In those specimens in which the inferior, or funicular, portion of the internal oblique is aponeurotic (Fig. 2) the true structure of the layer is evident. The stratum is complete, is attached, without breach or hiatus, to the inguinal ligament. It contains no "aponeurotic inguinal falx," i.e., no thickened falciform band exists (even where the layer is muscular) until the spermatic cord has been retracted and the cremasteric fibers sharply separated from those just above; the superior wall of the cleft thus produced is the only

Fig 2 Specimen B Dissection as in Figure 1. An uncommon type of internal oblique in which the inguinal part of the layer is more aponeurotic than muscular and almost entirely aponeurotic over the abdominal inguinal ring. The margin of the subjacent transverse muscle is indicated by broken line. The position of a hernia adiposa by arrow (Figs 3 and 4).

observable representation of a falx. Therefore, such a band must be regarded as an artifact, evident only after the musculofascial layer has been separated into two distinct parts, one above, the other below the cleft.¹

Actually, then, since the aponeurosis passes anterior to the rectus muscle the so called aponeurotic inguinal falx is merely an area in the anterior lamina of the rectus sheath rendered more prominent than the surrounding tissue through its insertion into bone. Directly posterior to this portion of the aponeurosis is situated the rectus muscle so that even if the falx were a markedly thickened band, it could not be reasonably described as a structure efficacious in preventing direct inguinal herniation of the abdominal contents.

Fig 3 Specimen B Continued. An aponeurotic trans versus abdominis representative in the proportion of aponeurosis to muscle of almost 20 per cent of the cases (Fig 7) unusual in the thinning of its medial part which latter is set off from the thicker lateral portion by a falx form edge (at broken arrow). The thinner stratum covers the hernia adiposa (at unbroken arrow). Aponeurotic inguinal falx wanting.

When sutured to the inguinal ligament in herniotomy, the so called falx—which is merely part of the rectus sheath—is subjected to undue traction in all stretching movements of the abdominal musculature, this condition may in part account for the frequency of recurrence in hernia. It is our belief that such traction might be obviated, in hernial repair, by suturing a flap of the aponeurosis of the external oblique muscle to that of the trans versus abdominis (see demonstration in Fig 1a), this is accomplished by using the cleft in the internal oblique as the route by which the two layers are brought into approximation. The full discussion of the technique and of the results of its employment will be found in the article by Dr. Leo Zimmerman.

Beneath the internal oblique proper is an accessory internal oblique muscle (Chouke), present in 40 per cent of 250 inguinal regions studied.² It has doubtless been mistaken in

Fig 4 Specimen B Dissection concluded Showing the heavy internal layer of investing fascia of the transversus abdominis muscle (transversalis fascia), which, in turn, is incised transversely to expose the preperitoneal layer of connective tissue (and the contained hernia adiposa, at arrow), incised vertically, to demonstrate its continuity with the fascial covering of the iliacus muscle. The muscle fibers of the transversus abdominis have been turned medially to a point where the transversalis fascia fuses with the aponeurosis of the transversus abdominis muscle

the past for the transversus abdominis muscle, and its unrecognized presence may account for the fact that usually the latter is described and figured as extending farther inferiorly than it actually does

TRANSVERSUS ABDOMINIS MUSCLE AND TRANSVERSALIS FASCIA

The transversus abdominis is usually more aponeurotic in the inguinal region than is the internal oblique, thus although in 97 per cent of the cases, the muscular part of the internal oblique extended inferiorly as far as the spermatic cord (Fig 6), in only 3 per cent did the muscular portion of the transversus abdominis reach that level (Fig 7), in 62 per cent, it terminated within the superior half of the inguinal region, in 7 per cent it did not reach the anterior superior spine of the ilium, that is, was not inguinal at all; in approximately 19 per cent of the cases the layer was almost as aponeurotic as the external oblique

Fig 5 Specimen C Dissection of inguinal layer, sectioned 5 centimeters above the superior border of the pubis. The aponeuroses of the external and the internal oblique muscles remain only at their medial and inferior borders. The rectus muscle has been retracted from the anterior lamina of the rectus sheath to demonstrate the manner in which the investing "rectus fascia" arises from the aponeurosis of the transversus abdominis muscle. The line of fusion of the aponeurosis of the internal oblique with that of the transversus abdominis is vertical, both layers are unbroken, there being no margin which resembles an "aponeurotic inguinal falx". The line of fusion of the three aponeuroses occurs within the territory of the anterior lamina of the rectus sheath, each contributing, to a different extent, to the formation of the latter (marked by +)

in the same subject, the muscle fibers terminating at or near the interspinous line.

In the medial direction, the limit of the muscular part of the layer also varies considerably. In only about one-half of the cases do the muscle fibers form the lateral two-thirds of the stratum in the inguinohypogastric area and the aponeurosis the medial one-third (Fig 7), as is quite consistently the arrangement for the internal oblique.

The medially placed tendinous plate is, in almost all descriptions, correctly termed aponeurosis; but, curiously enough, the inferior continuation of the same structure is called a fascia, or specifically, the "transversalis fascia". That the two are merely areas of the same layer is clearly evident in those cases—numerous in the laboratory, rare in books and journals—in which the muscle fibers terminate at a high level, leaving a broad expanse of the stratum entirely without

between the thickness of the transversalis fascia and the rectus fascia—a thin slip of fascia that originates from the fused aponeurosis of the transversus and transversalis fascia and passes medially to invest the rectus muscle (Fig. 5). This fascia of the rectus muscle is a distinct structure, entirely separable from the sheath of the same muscle, related to it only in being a derivative of one of the three contributory aponeuroses to the sheath. This thin envelope may be the “transversalis fascia” upon which some authors state that the rectus muscle rests. This layer is comparable to the fascia which forms the immediate investment of muscles in other regions of

the body, e.g., to the leaf of cervical fascia which divides to enclose the sternocleidomastoid muscle, to the layer of pectoral fascia (costocoracoid membrane) which splits to invest the subclavius muscle. Except for it, the rectus muscle rests posteriorly upon preperitoneal connective tissue. After having contributed this muscle fascia to the rectus, the aponeurosis of the transversus abdominis muscle forms, for a short distance, the only anterior component of the rectus sheath (Fig. 5); it is next joined by the aponeurosis of the internal, finally by that of external, oblique muscle. The latter conjunction is accomplished near the linea alba.

CLINICAL SURGERY

INGUINAL HERNIA

II. The Surgical Treatment of Direct Inguinal Hernia

LEO M. ZIMMERMAN, M D, F A C S, Chicago, Illinois

THERE is a tendency among surgeons to view the results of the operative treatment for inguinal hernia with complacency. This satisfaction, however, is found to be unjustified whenever the test of actual postoperative follow-up is applied. The results of surgery in direct hernia are particularly disappointing. In a recent publication, Andrews and Bissell presented statistics from their own and other clinics showing recurrences in over 25 per cent of the cases in those series of direct hernias in which follow-up examinations were made. On the basis of these figures, they confess the failure of surgery as a treatment for the usual forms of direct hernia and advise against surgery in these cases, particularly since the discomforts and dangers of an otherwise harmless condition may be aggravated by unsuccessful operation.

Acceptance of defeat by surgeons does not help to solve the direct hernia problem. The recognition of the type of hernia present, before the canal is opened, is frequently difficult, even if the diagnostic criteria described by Andrews are utilized. I must confess that my pre-operative impressions, derived from both the patients' complaints and my own findings, are wrong sufficiently often to make me unwilling to advise treatment on the basis of the type of hernia I expect to find. Andrews mentions the medicolegal aspect of the problem, with reference to the inability of direct hernia sufferers to obtain employment. The other side of the picture also merits consideration. Many of these cases develop during employment and are treated as compensable conditions. Confession of inoperability would imply permanent disability and create a tremendous insurance problem. The essential lesion in direct hernia presents difficulties which, though perplexing, do not seem insurmountable. They should challenge us, rather, to continue to seek new methods until a more satisfactory solution to the problem has been found.

In seeking an explanation for the distressingly high incidence of recurrences following operation

for direct hernia, one factor would seem to be the failure of many surgeons adequately to differentiate, in their treatment, between hernias of the direct and the indirect variety. Indirect hernia is recognized as a peritoneal protrusion through the internal inguinal ring, in which failure of obliteration of the processus vaginalis is at least an important, if not determining factor. Direct hernia, on the other hand, is an actual rupture or stretching of the structures forming the floor¹ of the inguinal canal. In view of the totally different etiology and pathology of the two forms of hernia, it would seem that an appropriately different attack would be indicated, directed in each case against the fundamental lesion present. Nevertheless, one sees in the literature, as well as in the operating room, the same procedures used for both types of inguinal hernia.

Although direct hernia is always an acquired lesion, it has a predisposing anatomical background of congenital origin. In a recent study of the anatomy of the inguinal region conducted in the Department of Anatomy of Northwestern University Medical School,² the internal oblique muscle was usually found to be a complete musculofascial sheet extending down to the pubic spine. A narrow cleft separated the cremasteric portion of the muscle from its main body. The space, therefore, between the lower arching border of this muscle and Poupart's ligament was completely occupied by the spermatic cord, and no portion of the inguinal floor was unsupported by muscle. The downward extent of the fleshy fibers of the transversus abdominis muscle was much more variable, but it almost always ended higher than did the internal oblique. Continuing downward from the free lower muscular border was an aponeurotic membrane which completed the musculofascial sheet of this layer. This aponeurosis, usually designated the transversalis fascia,

¹The term "floor" is used to designate the posterior wall of the inguinal canal in accordance with surgical usage. In the supine position, as on the operating table, the posterior wall does form the floor of the canal.

²Anson B J, and McVay, C B. The anatomy of the region of inguinal hernia. Elsewhere in this journal.

extended down to the inguinal ligament and lay deep to the spermatic cord. It is the layer which comprised the floor of the inguinal canal.

The arrangement described, which may be considered the usual or normal, coincides with that usually encountered at operation in patients with indirect inguinal hernia. Under these circumstances, the inguinal canal is only a potential space which becomes further narrowed when the internal oblique muscle contracts and approximates itself to the inguinal ligament. Direct hernia is, not surprisingly, rare in persons with this type of abdominal protection.

In some of the specimens examined, however, the arrangement was different. The lower border of the internal oblique muscle ended at a variable distance above the pubis, leaving a triangular area, the so called inguinal triangle, bounded by the lower free border of the internal oblique muscle, the rectus sheath, and Poupart's ligament, in which the floor of the inguinal canal was unsupported by overlying muscle. In the anatomical study referred to above by actual measurements of 95 unselected specimens Anson and McVay found the length of the medial border of the triangle to be

Length in cm.	No. of specimens	Length in cm.	No. of specimens
0	15	3 0	12
0 5	4	3 5	2
1 0	12	4 0	2
1 5	14	5 0	4
2 0	18	6 0	2
2 5	30		

The specimen from which Figure 2 in the article by Anson and McVay is taken is an interesting example of abdominal wall in which the lower most fibers of the internal oblique muscle are wanting. In this subject, a direct inguinal hernia was found on the left side. On the right side although no hernia was present the arrangement of the muscles was identical. Poly¹ found a similar absence of the lower fibers of the internal oblique muscle in 15 of 50 dissected specimens the free border inserting into the rectus sheath from 1 to 3½ centimeters above the pubic spine.

The arrangement just described coincides with the findings at operation in patients with direct hernia, and probably explains the genesis of the hernia. Several observers have recorded this muscular deficiency during operations for direct hernia using various methods for determining the size of the defect. Poly¹, in 1912, actually measured the size of the inguinal triangle with a graduated uterine probe in 100 unselected cases of inguinal hernia. In these cases were included both the direct and the indirect varieties of inguinal hernia. He found that the length of rectus

sheath comprising a side of the triangle was as follows:

Length in cm.	No. of cases	Length in cm.	No. of cases
0	2	4	27
1	7	5	9
2	31	6	5
3	25	7	2

Andrews (3) measured the inguinal triangle in a series of 20 direct hernias and found that the average length of rectus sheath bordering it was 5 centimeters. Ssosan Jaroschewitch traced the margins of the triangle on sterile glass with a sterile pencil during operations for both types of inguinal hernias. The muscular defect was always larger in direct hernias than in indirect ones of the same size. In oblique hernias the lower fibers of the internal oblique muscle ran more nearly parallel with Poupart's ligament, and formed an obtuse angle with the rectus sheath. In direct hernias the angle approached 90 degrees, as the course of the lowermost fibers was almost transverse.

For some time, I have been mapping the boundaries of the inguinal triangle at operation, by a slightly different method. Using a coarse meshed, wax impregnated gauze (paresine gauze), patterns are cut of the muscle defect. With only rare exceptions, in direct hernias a triangle of material size has been present, in which the limb formed by the rectus sheath has ranged from 2 to 7 centimeters. In indirect hernias, the triangle is long and narrow, its width coinciding almost with the diameter of the cord. It is usually possible to tell at a glance as soon as the aponeurosis has been divided, what type of hernia one is dealing with by the type of internal oblique muscle present.

From these repeated observations the conviction grows that the underlying predisposing anatomical basis for direct hernia consists of a congenital absence of adequate muscular support for the lower portion of the inguinal canal. This explains the fact that most men go through lifetimes of hardest labor without developing direct hernia, while others who are relatively inactive, have direct hernias before middle age is reached. It also accounts for the frequently bilateral distribution of direct hernia since the anatomical structure is usually symmetrical on the two sides. The objection might be raised that the muscle defect is secondary the lower end of the internal oblique having been pushed upward and attenuated by the pressure of the sac. This is disproved by the fact that similar defects do not accompany in direct hernias of the same or larger size. Nor is size of triangle proportional to the size or duration of the hernia. And in cases with well developed lesions on one side and beginning ones on the other a symmetrical triangular defect is found.

SURGICAL TREATMENT

The surgical treatment for inguinal hernia, whether of the oblique or the direct variety, usually consists of operation by the Bassini technique or one of its numerous modifications. The essential step in all these procedures is the suture of the internal oblique muscle¹ to the inguinal ligament. This newly formed floor may then be reinforced with one or more of the other layers of the abdominal wall. The inadequacy of these methods, so far as direct hernia is concerned, is attested by the high incidence of recurrences in their wake. There are two apparent reasons for these failures. First, the rent in the floor of the canal, that is, in the transversalis fascia, which is the basic lesion in direct hernia, has not been repaired. Suturing the heavier overlying muscles gives the operator a false sense of security as to the adequacy of his repair and often leads him to omit the one step that logically should initiate any operation for direct hernia.

The second reason for the inadequacy of the conventional operations lies in the failure of permanent union between the internal oblique muscle and Poupart's ligament. Experience and experiment have repeatedly shown that confidence in the permanence of such union is misplaced. Seelig, Gallie and LeMesurier (6), and others have demonstrated that muscle and fascia do not unite firmly when sutured together. At reoperation in recurrent hernias, almost invariably, these structures are found to have returned to their original positions, as if they had never been sutured.

The essential problem in the repair of a direct hernia is the closure of a defect in the fascial floor of the inguinal canal. The predisposing cause of this rupture, as stated, is a congenital absence of adequate muscular support. Inasmuch as there are no methods by which muscle can be made to grow where it is deficient, the defect must be repaired by some type of fascial plastic procedure which will provide sufficient resistance to withstand the intra-abdominal pressure. To be effective, the fascial reinforcement should be in

immediate apposition with the newly repaired transversalis fascia. There should be contact between the two layers over a broad surface, without tension and with no interposition of muscle or fatty tissue.

There are several methods by which these requirements can be fulfilled. They are approximated in the "white fascia" operation of Andrews (1, 2). Here, however, the reinforcing aponeurosis is separated from the transversalis fascia by whatever internal oblique muscle there is, and it still lies in the position of the roof of the canal rather than the floor. The method of fascial strip plaiting popularized by Gallie and LeMesurier (7) has found wide adoption. This operation, however, is not easy. It requires a separate intervention to provide the fascial strips. The fascial sutures are cumbersome and necessitate very coarse needles with their attendant trauma to the tissues they penetrate. The strips have been detached from their blood supply and thus act as foreign bodies. The incidence of infection in reported series of such operations is material. That this procedure is not the final solution to the problem of difficult hernia is attested by the recent publication of Burdick, Gillespie, and Higinbotham in which a recurrence rate of 29.1 per cent was reported in a total series of almost 1500 cases operated upon by the fascial strip method. There were 310 primary direct inguinal hernias in this series with recurrences in 25.8 per cent.

Other methods of fascial transplantation include the free transplantation of autogenous or preserved fascia. The former is preferred for obvious reasons, and we have used it to good advantage in difficult recurrent hernias. The fascial patch is taken from the fascia lata of the thigh and insinuated between the transversalis fascia and internal oblique muscle. Its disadvantages lie in the fact that a second incision is required and the transplant is detached from the sources of its blood supply.

Pedunculated fascial flaps have also been used for hernial repair. Turner has recommended cutting a rectangular flap from the fascia of the thigh, just below Poupart's ligament, which is left attached superiorly. The inguinal ligament is then separated from the femoral vessels, and the flap is turned up under the ligament, to cover the inguinal region. Unfortunately, the fascia lata is weakest at this point, and is perforated at the fossa ovalis for the passage of the saphenous vein. The inguinal lymph nodes lie on the fascia in this region, interference with which might prove disastrous. Furthermore, there is danger to the femoral vessels both during the operation and in leaving

¹The term "conjoined tendon" is omitted advisedly because it is incorrect and confusing. Two separate structures are described bearing this name. In anatomical descriptions, it is defined as the "aponeurotic inguinal falx," a fasciofascial band of fascia derived from the insertions of both the internal oblique and transversus abdominis muscles, which attaches to the pubic crest, tubercle, and laterally along the pectineal line for a distance of 3.75 centimeters. It lies deep to the spermatic cord and reinforces the transversalis fascia in forming the posterior wall of the inguinal canal. As stated in the article by Anson and McVay, a careful anatomical study revealed no such structure.

In surgical literature, the term "conjoined tendon" usually refers to the lower arching fibers of the internal oblique muscle. As pointed out by Anson and McVay, this free margin is actually an artefact. It is almost invariably muscular rather than tendinous, at least in part, and it does not fuse with the insertion of the transversus abdominis for some distance medial to the edge of the rectus muscle. In other words, it is neither conjoined nor tendinous. The interests of clarity would be better served, therefore, if the term "conjoined tendon" were abandoned.

them without their fascial protection. The procedure of Wangenstein, of turning up a pedunculated flap of fascia lata with its attached tensor muscle is of unquestioned value in repairing huge abdominal or inguinal defects. It is too extensive a procedure, however, for the ordinary hernias, even of the direct variety.

For several years I have used a simple plastic step which apparently meets the requirements for the repair of most direct hernias. The method consists of first freeing and closing the transversalis fascia, then reinforcing it with a patch from the lateral flap of the external oblique aponeurosis. This portion of the aponeurosis is usually present as a firm white fibrous structure, many times stronger than the original fascial floor of the inguinal canal. The flap retains its normal attachments, so that its circulation and its viability are unquestioned. It is insinuated between the transversalis fascia and the internal oblique muscle, in direct apposition with the former structure. There is, therefore, broad approximation of fascia to fascia without interposed muscle tissue. The operation is technically easy, requires no second incision or wide dissection and takes no more time than the usual methods of herniorrhaphy.

TECHNIQUE

The steps of the operation are illustrated in Figures 1 to 7. The usual inguinal incision is made and the canal is opened by dividing the aponeurosis of the external oblique along the medial crus of the external ring in order to provide a lateral flap wide enough to be used later for covering the hernial defect. The spermatic cord is dissected to rule out a concomitant indirect hernia and is then retracted laterally. The direct hernial sac is gently lifted with forceps and freed in its entire circumference by dividing with dissecting scissors the attenuated fascial fibers coursing over it. When it has been completely liberated, a free border of transversalis fascia, extending from the pubis to the deep epigastric vessels has become defined.

The sac, as a rule, is wide and dome shaped and is often covered with a thick layer of extra-peritoneal fatty tissue. Since it is merely the presenting portion of the peritoneal lining bulging through the weakened floor, and not the essential constituent of the hernia nothing is gained by opening removing suturing, or plating the sac. Its proximity to the bladder renders such steps dangerous as well as unnecessary. Instead, the sac is merely inverted into the retroperitoneal space, and the transversalis fascia is sutured down to Poupart's ligament over it. Because of the

mobility of the transversalis fascia, this can always be accomplished without tension. When completed the floor of the canal from the pubic spine to the inferior epigastric vessels has been restored and the hernial bulge disappears from view.

The newly reconstructed floor is then reinforced (Figs. 5, 6) with a flap cut from the outer leaf of the aponeurosis of the external oblique muscle. This aponeurotic flap is incised obliquely from above downward, opposite the internal ring and the patch thus formed is swung beneath the cord. The internal oblique muscle is gently elevated on a blunt retractor, and the patch insinuated between it and the subjacent transversalis fascia. It is fixed with interrupted sutures and the muscle is allowed to fall back to its normal position covering the suture line as a trapdoor. No sutures are placed in the muscle layer.

In those instances in which the insertion of the internal oblique muscle is fibrous rather than muscular, the cleavage plane between it and the transversalis fascia is less well defined. Nevertheless, in the anatomical studies referred to, it was found that these layers can always be separated without difficulty. If, however, in such cases the flap were to be brought anterior to the internal oblique aponeurosis, union would probably take place since both layers are fascial.

The final step in the operation consists in dropping the cord back upon the strongly reinforced inguinal floor and restoring the roof of the canal. This is done by bringing the medial flap of the external oblique aponeurosis over the cord and suturing it to the external surface of Poupart's ligament (Fig. 7). To avoid relaxation of the wall at the site of division of the lower flap an imbrication stitch is placed at this point and the upper flap is brought down over it with a continuous suture. To reconstruct the external ring this suture ends with a pursestring in Scarpa's fascia bringing it snugly about the cord at the lower end of the canal. In the occasional subject in which the lower flap of the aponeurosis seems inadequate as a reinforcement for the inguinal floor the upper flap may also be brought beneath the cord leaving the latter structure immediately beneath the skin. The cutaneous incision, finally, is closed and a pressure spica of elastic bandage or stockinette is applied.

The operation can be done under local or general anesthesia. It requires relatively little time for its completion and inasmuch as no tension is required in placing the sutures there is no contra-indication to operating upon both sides of a bilateral hernia at the same sitting. In such

instances, a single transverse, suprapubic incision joining the upper margins of the external rings may be used with advantage. As Andrews has pointed out, the purely fascial herniorrhaphies are followed by relatively little postoperative pain. In repairs of the type described, it is not at all uncommon for patients to go through the entire postoperative period without requiring opiates for relief of pain.

When brought from the operating room, the patients are placed in a slightly flexed position, by elevating the backrest and raising the knees to avoid the discomfort from tension on the wound. Fluids are allowed post nauseam and food as soon thereafter as desired. The patients are permitted to be out of bed as soon as pulse, temperature, and general condition warrants. This usually means from 1 to 3 days in bed. The average period of recumbency is about 48 hours. The patients walk as early as they wish and are discharged from the hospital 7 to 10 days after the operation. Work is resumed any time after 4 weeks. As a rule, no limitations are placed upon the type of work done and no supports are prescribed except in elderly patients, in recurrent cases, or in unusually large hernias.

RESULTS

The operation above described has been done in 90 consecutive direct hernias during the past 6 years. Every effort has been made to follow these patients by actual personal periodical re-examination, for as long a period as possible after operation. Of the total number, I have been able to follow 59 for a minimum period of 1 year. The interval between operation and the latest examination in these cases has been:

Follow-up mos	Cases
12 to 18	20
18 to 24	6
24 to 30	10
30 to 36	7
36 to 48	10
Over 48	6
Total	59

In these 59 cases which have been followed for a minimum period of 1 year, there have been 6 recurrences, an incidence of 10.2 per cent. This figure, while still high, compares very favorably with that usually reported in similarly controlled series of direct hernias treated by conventional methods. Nor is this figure to be looked upon as the irreducible minimum. It is significant that 3 of the 6 failures occurred during the first year the method was used, which would suggest that technical considerations were partly responsible.

The exercise of some selection of the cases to be treated would probably further reduce the incidence of recurrence. This does not imply, however, a return to the orthodox procedures, but rather that even more radical methods be used for the most difficult and unfavorable cases.

It is of interest that 5 of the 6 recurrences were in patients with bilateral hernias, and all developed within a year following the operation. Four of these patients are working and apparently are not seriously incapacitated because of the hernias. I have re-operated upon the 2 others. One, an obese middle-aged man with bilateral hernia, was found to have a diffuse bulging through the inguinal floor. The fascial flap had apparently healed in place, but was of insufficient strength to withstand the abdominal pressure. The other originally had a diverticular type of direct hernia. At re-operation, a small, well defined hiatus in an otherwise firm fascial floor was found.

ADEQUACY OF METHOD

In principle, adequate repair of direct inguinal hernia requires, first, the closure of the defect in the transversalis fascia which constitutes the essential lesion. This fascial layer must then be strengthened by superimposing upon it a patch of firm, fibrous tissue. If a pedicled flap is used, it should be brought up from below, since any such flap derived from the upper leaf of the external oblique aponeurosis or the rectus sheath would, of necessity, be separated from the transversalis fascia by whatever internal oblique muscle there is.

The method described fulfills these requirements. It consists of isolation and reduction of the sac without opening it; of suture of the transversalis fascia to the inguinal ligament; and of reinforcement thereof with a flap derived from the lateral leaf of the aponeurosis of the external oblique. Only white fascia is used throughout, and the fascial layers are approximated to one another over a broad surface, without tension, with no interference with their blood supply, and without the interposition of muscle. The mobility of the transversalis fascia permits its being brought down to the inguinal ligament without difficulty. The outer leaf of the external oblique aponeurosis is almost invariably present as a good, firm, fibrous structure, from which the reinforcing flap may be taken. If this layer appears inadequate, it may be supplemented with the upper leaf of the aponeurosis. If the defect to be closed is too large, or the available tissues inadequate, the answer cannot be found in a return to the usual hernial operations, but must be sought in some type of

more radical transplantation as, for instance, of the iliotibial tract

SUMMARY

The usual operations for direct hernia are inadequate, as is indicated by the high rate of recurrences recorded whenever follow up studies are made. Their failure lies in neglecting to repair the defect in the floor of the canal, and in their dependence upon union between muscle and fascial tissues. A simple procedure is described in which the fascial floor is first sutured, then reinforced with a flap of firm fibrous fascia derived from the outer leaf of the aponeurosis of the external oblique muscle. No sutures are placed in the internal oblique muscle. The fascial structures are approximated over a broad surface, without tension and without the interposition of muscle. This method meets the requirements for most direct hernias. It has been used in 90 consecutive direct hernias during the past 6 years. Actual follow up re examinations at intervals ranging from 1 to 5 years in 59 cases revealed 6 recurrences, an incidence of failure of 10.2 per cent.

TOTAL TENDON TRANSPLANT FOR SLIPPING PATELLA

A New Operation for Recurrent Dislocation of the Patella

EMIL D. W. HAUSER, M D , F A C S , Chicago, Illinois

RECURRENT dislocations of the patella (slipping patella) may be divided, for clinical purposes, into three types: (1) congenital, which is a true anomaly; (2) traumatic, which is the result of severe injury, and (3) rachitic, which is secondary to a marked genu valgum

The anomalies that occur in the congenital type are not confined to the patella but frequently involve the patellar ligament and the lower end of the femur. The posterior surface, instead of having two equal joint surfaces to glide over the condyles of the femur, is irregular sometimes to the point of being almost wedge-shaped. The surface of the lateral condyle over which the patella glides is flattened and altered from the normal rounded shape, and since it is not fully developed the patella is likely to displace laterally. The patellar ligament is lengthened and the attachment to the tibia lies lateral to the normal attachment. The outer strands are much stronger, while the medial strands have become weakened through disuse, often to the point of atrophy and ultimate loss. The lengthening of the patellar ligament results in a high position of the patella in relation to the knee joint. The effect of this position on the function of the knee joint will be explained later. Congenital anomalies vary in severity, at times being so mild as not to cause any serious disturbance in function. Frequently both knees are involved; sometimes the one may give rise to recurrent dislocations, while the other, even though markedly deformed, carries out its function without any disability.

The traumatic type of recurrent dislocation of the patella is relatively rare. It occurs as the result of severe injury which is practically always an indirect trauma. Most frequently it is the result of a forceful twist which brings the leg into abduction at the knee, with a resultant tear not only of the medial ligament of the knee but also of the entire medial fascia, so that the patella and patellar tendon are displaced laterally. Such a knee if permitted to heal with a gap in the fascia, particularly near the upper part of the patella, has a tendency to recurrent dislocation. A

traumatic recurrent dislocation of the patella, if allowed to go untreated indefinitely, gives rise to secondary changes in the quadriceps muscle, in the lateral ligament, and in the patellar tendon, and ultimately in the patella itself. These changes are the result of altered use and a certain amount of disuse. The quadriceps muscle becomes weak and atrophic; the patellar tendon is lengthened and displaced laterally; the lateral fascia and capsule are shortened and markedly thickened. The shape of the patella is altered; it becomes wedge-shaped, the thinner part being toward the medial margin and the base toward the outer margin. A severe, neglected, traumatic recurring dislocation of the patella may ultimately reach the point where it becomes chronic, that is, the patella becomes constantly dislocated with nearly complete loss of function.

The rachitic type of slipping patella is associated with a primary anatomical change, namely, a genu valgum. That some other factor plays a rôle is evident, for not all patients with genu valgum are subject to recurrent dislocations of the patella; however, a severe genu valgum and a lengthened patellar ligament will explain a recurrent dislocation of the patella. In severe deformities the lateral condyle may be immaturely developed, particularly on its anterior surface, so that the patella can slide over to dislocate.

REVIEW OF LITERATURE

Prophylaxis and conservative treatment are not considered in this paper. Before presenting the new type of operation for slipping patella and its advantages, it is pertinent to discuss the operations previously used and their shortcomings, as well as the prerequisites of the operation of choice, so that the operation which is to be described and recommended may be evaluated on the basis of definite criteria.

Numerous operations have been described for correction of recurrent dislocation of the patella. The number in itself predicates that the problem has not been solved. No attempt will be made to give a detailed description of each individual operative technique however, in order to give fair consideration to each and every procedure that has been devised, the methods have all been

reviewed and will be discussed under groups arranged according to anatomical classification.

The various types of operation are divided into 6 groups namely (1) those procedures which are directed against the relaxed median capsule, (2) those in which the fascia is transplanted, (3) those in which secondary muscles are used to hold the patella medially, (4) those in which free fascial transplants are used to hold the patella medially, (5) those in which the lower end of the femur is attacked, and (6) those in which the patellar ligament is transplanted.

Under the first group we consider the so called reefing of the median capsule and fascia. In the very earliest of this type of operation, the medial side of the capsule was scraped and scarified in order to bring about a contracture (Heller, 1850). The next procedure was to reef the median capsule and fascia (Hoffa and Gocht). This method was soon found to be insufficient to prevent recurrence, so the patella was freed at its lateral margin before the reefing was done (Tubby). Attempts were made to free the patella and to hold it in the medial displacement (Perkins) while Wright sutured the patella to the medial condyle. The benefit attained was ascribed to scarification (Schanz). Later emphasis was placed on extending the incision of the lateral fascia well up along the margin of the conjoint tendon (Perthes). To shorten the fascia and ligament on the medial side the longitudinal incision was made through the fascia, the margins were undermined and overlapped, imbricated and sutured (Murphy). The vastus internus was imbricated in a similar manner along with the fascia (Bevan—Fig 1 A).

These methods proved inadequate because, first they did not prevent recurrence of the dislocation in a high enough percentage of cases second, they did not correct the high position of the patella third, they did not offer any correction of the lengthened patellar ligament fourth, they did not keep the muscle pull of the quadriceps in a direct line so that it can exert its greatest force in carrying out normal function.

The second group attempted the correction by means of a transplant of the fascia. First an oval section was removed from the joint capsule on the medial side and this was then closed with sutures, drawing the patella medially (LeDentu). This operation was also combined with a reefing of the capsule. It was found necessary in many cases to make a second incision lateral to the patella through the fascia. With the drawing of the patella medially an open space resulted at the site of the incision. This was filled in by means

of a transplant removed from the medial ligament (Dickson—Fig 1, C). The best technique for carrying out this procedure is to transplant a long strip of the medial capsule, the fascia, and the vastus internus over the upper margin of the patella into the gap on the lateral side (Krogus—Fig 1, B). This was also used by others (Strater, Lorenz, von Ruediger, Rydygier, Klapp and Lueckerath). This type of fascial graft can be combined with a muscle graft (Frangenheim). Another type of fascial plastic operation includes the transplant from the inner side of the capsule to the external side with a reefing of the medial capsule and a shortening of the quadriceps (Conn). This second type of operation again permitted recurrences although in a smaller percentage of cases than with the first group (Kapel). The patellar ligament is not shortened by this method and, therefore, the patella does not assume its normal position. Furthermore, this type of operation is not applicable to the severe cases in which the patellar ligament inserts too far laterally on the tibia since it does not bring about a direct pull of the quadriceps upon the tibia thus permitting the ligament to shoot off at a marked angle from the patella to the tibia.

The third group comprises those operations which attempted the correction by operations upon the muscles particularly by means of transplants. An attempt was made to shorten the quadriceps by reefing the tendon and fastening the aponeurosis of the internal vastus to the patella under tension (Bardenheuer). This method was used by others (Hoffmann and Bunts). The direction of pull of the quadriceps was altered by fastening the semitendinosus to this muscle (Heusner). In addition to the semitendinosus, the gracilis was also fastened to the quadriceps by drawing it through the fascia of the vastus internus (Lanz). The gracilis was also fastened on to the patella in addition to reefing the capsule and transplanting the insertion of the patellar ligament medially (Whitelocke). The sartorius muscle was brought around the quadriceps tendon and fastened into the medial condyle. In this way the sartorius acted as a sling to hold the patella medially (Hoffa and Gocht). A combination of fascial plastic and tendon transfer from the outer to the inner side has been attempted (Pasquale del Torto). The object of these muscle transplants was an attempt to strengthen the weakened quadriceps and to draw the patella medially. The objection to this method, aside from being a highly involved procedure and technically difficult to execute is that the mechanical forces that draw the patella laterally are much greater than

Fig. 1, A.

Fig. 1, B

Fig. 1, C

the combined power of all the muscles that can be transplanted. The results are very uncertain. The procedure has been discarded because of the frequency of recurrences (Fig. 1, B).

The fourth group consists of fascial transplants. A strip of fascia lata or peroneal tendon was fastened to the patella and to the medial condyle of the femur (Gallie and LeMesurier). Others have used this operation with success (Ryerson) and still others recommend it for selected cases (Cole and Williamson). The fascial strip removed from the lateral side of the knee was run subcutaneously over the patella and fastened to the medial condyle (Klapp). This operation was also used by other authors (Karl and Hartleib). The

Operation of Dickson (Typical of Group 2) (A, from Murphy, Clin. John B. Murphy, B, from Krogus, Zentralbl. f. Chir.; C, from Dickson, Surg. Clin., North America)

iliotibial band was passed beneath the aponeurosis and sutured to the medial aspect of the tibia (Ober). A strip of fascia was used to encircle the patella and both ends fastened to the iliotibial tract and the medial condyle (Vorschuetz). A strip of fascia lata was run through a tunnel in the patella and fastened to the tibia to form a new patellar ligament (Soutter). Wilson used silk for a ligament. To correct the patella from above and hold it in alignment, the quadriceps tendon was fastened on to the gracilis muscle by means of a fascial ring (Rene Sommer). An Italian surgeon also did a reconstruction of the quadriceps tendon. Criticism of this method is that active forces, namely, the lateral pull of the quadriceps, continues to act against the ligamentous transplant which may, even if in relatively few cases, stretch or give way with resultant recurrence of the dislocation. Second, it does not correct the high position of the patella nor shorten the lengthened patellar ligament, therefore, it does not re-establish normal function of the quadriceps muscle.

The fifth group of operations comprises those upon the lower end of the femur. To prevent the patella from slipping laterally, an oblique osteotomy was performed which permitted a straightening of the leg and rotation into normal position (Graser, Huebscher). An osteotomy

from behind forward and from forward above was devised which lengthened the femur and put tension on the quadriceps (Hacker)

To prevent the patella from slipping laterally the external condyle was raised by means of an osteotomy (Sir Robert Jones). The external condyle was raised and an ivory peg inserted (Trendelenburg). Also the upper end of the

fibula was utilized (Boehler) and a wedge-shaped tibial graft has been employed (Albee—Fig 3, A). This last type of tibial graft has been combined with plication (Buzby). In extreme cases of genu valgum it may be necessary to carry out the correction by means of a supracondylar osteotomy. Attempts to prevent the slipping of the patella have not always been successful since the quadriceps pull remained laterally in spite of the correction (W. B. Owen). Furthermore, the quadriceps is shortened as a result of bone lengthening and this leads to limitation of flexion at the knee (Finsterer). The operation requires prolonged fixation and would, therefore, not be the operation of choice. With regard to the elevation of the external condyle, this is an ingenious device for those cases in which the slipping is due to the underdevelopment of the external condyle. It necessitates opening the joint. It would not effect a lowering of the patella and shortening of the patellar ligament, and thus would not re-establish the normal capacity of the quadriceps. Good results, however, have been reported with both methods (Drehmann, Schanz, Albee).

The sixth type of operation consists in transplanting the patellar ligament. The ligament was split in half, the outer portion drawn under the inner half and fastened through a drill hole in the median side of the tibia (Goldthwaite). Some refinement of this technique was made by MacAusland. The patellar ligament was freed from its insertion and transplanted to the inner condyle of the tibia by excising a triangular piece of periosteum. At the same time the vastus lateralis was divided because it was stronger than the vastus medialis. The fascia of the vastus medialis was reefed (Roux) which increased the tension on the quadriceps muscle. The inner third of the patellar ligament has been split and fastened medially and distally to the tibia under the periosteal bridge (Huebscher). The entire ligament has been transplanted medially (Bade and Parker) and at the same time drawn distally to a level lower than the ordinary insertion. A triangular transplant with its base at the insertion of the patellar ligament is swung from the medial side of the knee to the lateral side (Frank Forty). Camera transplanted the patellar ligament medially and at the same time did an osteotomy of the femur to correct the genu valgum. The patellar ligament has also been fastened by a wire nail (Sir Robert Jones). A block which included the attachment of the patellar ligament has been cut from the tibia and forced to slide medially, thus bringing about a medial transplant of the ligament (Kirschner). Plication of the medial

capsule has been done in connection with patellar ligament transplants (Davis). In the congenital type of dislocated patella with contractures in the lateral fascia and capsule, the procedures mentioned will not be adequate since they do not bring the quadriceps pull in direct line to the tibia. The quadriceps force continues to pull laterally and to act as an opposing force against the transplant. Furthermore, the patellar ligament runs at an angle from the patella to the tibial insertion. The force acting in this manner for a long period of time will tend to cause a rotation of the tibia which will result in a deformity of the leg.

Another original method of treatment to prevent dislocation of the patella has been to place a bone block taken from the patella itself in the external condyle of the femur (Estor and Estor). Costal grafts have also been used for this purpose (Rocher—Fig. 3, B).

Judging from the recent literature, the present tendency is toward some type of transplant operation. In one such operation there is a complete transplant of the quadriceps extension apparatus with incisions down into the joint. Then a transplant after the manner of Krogus is carried out with a medial shifting of the entire patellar insertion (Fevre and Dupuis, Voelcker, Dencks, Herlyn—Fig. 1, B). Another method is to make an incision along the patella on both sides, cutting down right through the joint. Then the patella and the medial side of patellar ligament are sutured so that the quadriceps tendon comes back into the midline. This leaves a gap on the lateral side which opens down into the joint. The patellar ligament is transplanted medially and fastened with a nail. The gap is allowed to remain open (H. Strube). In a similar manner the outer margin of the vastus externus and both sides of the patellar tendon were freed and a raw surface made on the inner side of the tibia. The muscle and tendon were displaced inward and sutured, and the surplus capsule was transferred from the inner to the outer side of the joint (Malkin). Another type of procedure is to dissect the patella and the patellar ligament and its insertion so that they are entirely free. Then a slit is made in the middle of the capsule of the knee joint through which the freed patella and patellar ligament are drawn. The opening in the capsule is closed with interrupted sutures. The bony attachment of the patellar ligament is then screwed on to the tibia, and the patellar ligament and patella are fastened to the original capsule of the ligament (Mouchet and Durand—Fig 3, C). The objections to these operations are first, that they necessitate exten-

Fig 3 A Bone graft used to elevate the lateral condyle (Operation of Albee) B Bone graft inserted into the lateral condyle to prevent slipping patella (Operation of Estor) C Operation of Mouchet and Durand. Patella

sive opening and suturing in the joint surface which increases the operative risk, second, they are complicated, third, the introduction of a metal screw or nail is not necessary, and finally, the position of the patella is not lowered so as to assume a normal position for leverage at the patella nor to restore normal muscle tension to the quadriceps muscle apparatus.

CRITERIA OF A SUCCESSFUL OPERATION

The criteria of a successful operation have been indicated in the above objections to previous operations. The prerequisites of an operation for correcting recurrent dislocation of the patella are: (1) the prevention of recurrence, (2) the feeling of absolute security on the part of the patient, (3) the

re-establishment of the full functional capacity of the knee joint, (4) the normal appearance of the knee, (5) the minimum risk to the patient, and (6) the short period of convalescence. Judged by these criteria, a review of the operative procedures that have been described up to the present time shows that no procedure devised so far has entirely fulfilled the requirements demanded by an operation that will assure both a satisfactory correction of the anatomical changes and restoration of normal function.

In order to meet the requirements of an anatomical correction for all types of recurrent dislocation, it is necessary to re-establish normal pull of the quadriceps muscle from its origin to its insertion. This includes the replacement of the

Fig 5 Total transplant operation (author's method) A left Shows the mobilization of the quadriceps apparatus and the removal of the corresponding block medially and distally to the original attachment of the patellar ligament on the tibia B Shows the graft countersunk The periosteum is sutured over the graft and the patellar ligament is sutured laterally with reefing of the medial fascia and capsule The quadriceps is in a straight line of pull and the patella is lowered

patella into its normal groove as well as the attachment of the patellar ligament to the patella so as to bring the line of pull directly through it to the ligament. The patella must be drawn down to its normal position with regard to its relationship to the knee. It is also important that the quadriceps tendon is not displaced but lies in the midline. Probably more important than any one of these factors is the fact that the upper margin of the patella must be brought over to the midline for it is here that the greatest force is exerted in weight bearing when the knee is flexed. Finally to re-establish normal capacity of the quadriceps muscle it is necessary to have normal tension, which means that, if patellar ligament is lengthened it is necessary to lower its insertion or somehow to shorten the mechanism of the quadriceps pull.

AUTHOR'S OPERATION

The operation about to be described was first performed 5 years ago and has been used in every case of recurrent dislocation that has come to my care since that time. Although the number is still small, the results have been uniformly successful. Four cases are reported in 2 of which there were bilateral congenital dislocations. The operation is applicable to the most difficult as well as to the simpler cases of the congenital and traumatic types. For the rachitic type with marked genu valgum the operation of choice undoubtedly is the correction of the genu valgum by means of a supracondylar osteotomy.

The technique of the operation referred to is as follows (Figs 4 and 5). A curved incision is made, starting above the upper lateral margin of the

Fig 6 Case 1 G V A, Roentgenogram of right knee, anterior view, showing the patella laterally displaced and riding high B, Lateral view of the same knee. C, Roentgenogram of the same knee after operation. (Film reversed) Anteroposterior view shows patella more medial and lower D, Lateral view shows knee slightly bent and patella remaining low.

patella, curving laterally around the patella, and coming back to the midline about one-half inch below the tubercle of the tibia. The skin is freed on both sides to expose the patella, the conjoined tendon, and the patellar ligament. The patellar ligament is then dissected free down to its insertion. A block of bone about one-half inch square, including the attachment of the patellar ligament, is removed from the tibia by means of the electrical saw on three surfaces and an osteotome on the upper surface under the ligament. The entire lateral side of the patella is then dissected free by dividing the fascia down to the capsule. The dissection is carried along the lateral side of the conjoined tendon, well up into the area of the fascia lateral to the vastus muscle, this thickened fascia is divided down to the capsule but the operation remains extra-articular. The patella can now be drawn medially. The insertion of the patellar ligament is drawn to the median side of the tibia and distally until the patella lies low in the normal position between the condyles, this requires some tension of the quadriceps muscle. The periosteum is incised to make two flaps which are reflected. Then, a bony block one-half inch square is removed from the tibia in this area by means of the electrical saw. The attachment of the patellar ligament and its block are countersunk in this space, and the periosteum is then sutured over the block. The second graft is then fitted into the space at the tibial tubercle. Three sutures of No. 1 chromic catgut act as

further stays to hold the medial side of the patellar ligament to the periosteum. The stretched medial fascia is then reefed in the region of the upper margin of the patella. It is not necessary to transplant the fascia to fill in the gap on the lateral side. The skin is closed. The fixation is held by means of a plaster-of-Paris cast for from 10 to 14 days. The sutures are removed at the end of this period, after which the quadriceps muscle can be massaged and weight-bearing started, with the leg extended. The fourth week following operation the knee can be flexed and the quadriceps muscle allowed to contract voluntarily. Free flexion is permitted after 6 weeks.

A similar operation has been devised and executed by M. S. Henderson of the Mayo Clinic (personal communication), without emphasis on lowering the insertion of the patellar ligament.

The operation has proved satisfactory and apparently has the advantage of being a true reconstruction type of operation which permits early use and assures increased strength, as well as being applicable to both congenital and traumatic types of dislocation.

The principle of the operation fulfills all the requirements laid down as criteria for a successful operation in cases of slipping patella. It accomplishes full correction of the anatomical deformity, which includes the transplant of the quadriceps tendon, the patella, and the patellar ligament, so there is a direct line of pull in the quadriceps muscle system. It assures the proper position of

the patella both in regard to the condyles and in relation to the knee. Furthermore the upper margin of the patella is in the midline so the force acting there has no tendency to displace it laterally. The tension of the quadriceps muscle can be controlled so that the proper tension is permissible. The case histories of the patients operated upon will further establish that there have been no recurrences that the function has been returned to normal, that in some cases the capacity has been increased beyond that of the other knee and finally as volunteered by the patients, that the knees feel absolutely secure at all times.

CASE REPORTS

CASE 1. Congenital anomaly of the knee with osteochondritis dissecans possible and probably a loose body in the knee plus a slipping patella.

G V (Clinic No. 274669) 27 years of age was admitted to St. Luke's Hospital on July 15, 1931, complaining of a painful weak knee which would catch. Patient stated that ever since childhood he had had trouble with his right knee that something apparently would slip out of place in the knee and he would fall down. This occurred frequently and was followed by acute pain in the knee. During the last few years these attacks were associated with swelling in the knee. He had sought relief in many clinics throughout the country. He stated that in no instance was any surgery suggested that he was advised that

nothing could be done and that he would have to put up with his disability. During the 2 years preceding his admission to the hospital the attacks of a sharp catch in the knee had become more frequent and more severe and he had been unable to depend upon the knee with any degree of security. Past history included typhoid fever, scarlet fever, mumps, whooping cough and influenza, excision of a right cervical lymph node and tonsillectomy at the age of 14. His father died of angina pectoris; his mother was living and well; he had no brothers or sisters.

Physical examination showed a well-nourished white male, apparently comfortable, who was able to walk into the hospital. Pupils reacted normally; teeth were in good condition; tonsils cleanly removed. Neck was entirely negative save for a slight scar; lungs normal; abdomen negative. The patellar reflex was normal. Examination of the right lower extremity showed atrophy of the quadriceps with a slight decrease in the circumference of the thigh as compared with the left. The patella was movable in a wider range than normal and movement was associated with pain. A clicking could be felt over the knee when it was flexed and extended. Both patellae were smaller in circumference and thicker in diameter than one would normally expect.

Wassermann test was negative. Urinalysis was negative. Blood count showed 5,010,000 erythrocytes, 17,550 leucocytes and hemoglobin 20.2 grams. X-ray examination of the knee showed a defect on the posterior surface of the patella which suggested an osteochondritis dissecans.

The pre-operative diagnosis was congenital anomaly of the knee with osteochondritis dissecans possible and probably a loose body in the knee plus a slipping patella.

The following operation was performed:

A

B.

C

D

Fig 8 Case 2 E D A, Roentgenogram made before operation anteroposterior view. Patella is lateral and high. Lateral condyle is underdeveloped. B, Lateral view. Note that the patella is high and there is a large loose body between the patella and femur. C, Roentgenogram made after operation (film reversed) showing patella in center. D, Lateral view showing the patella lower and loose body absent.

A curved incision was made, starting above the upper lateral margin of the patella and curving laterally around the patella to come back in the midline about one-half inch below the tubercle of the tibia. The skin was freed on both sides to expose the patella, the conjoined tendon, and the ligament. The patella was found to be displaced laterally. The knee was then opened through an incision on the medial side, about an inch and one-half in length. The inner surface of the knee was examined for loose bodies, the posterior surface of the patella was examined and found to be roughened. The patella was everted to obtain a more satisfactory exposure. The posterior surface showed a demarcation which suggested an osteochondritis dissecans with a fragment loosened but still attached, the attachment was so firm that it resisted prying with a chisel and was, therefore, left intact. The knee was closed. The patellar ligament was then dissected free down to its insertion, the insertion of the ligament was freed by the removal of a block of bone about one-half inch square, which included the attachment of the ligament. The entire lateral side of the patella was dissected free by dividing the fascia down to the capsule. This dissection was carried upward along the lateral side of the conjoined tendon into the area of the fascia lateralis. The patella could then be easily drawn medially. The insertion of the patellar ligament was drawn to the medial side of the tibia, and distally until it was about $1\frac{1}{2}$ inches below its former insertion. At this point the periosteum was incised to make two perosteal flaps which were reflected. The bony block and the insertion of the patellar ligament were fastened so that both surfaces were in contact with raw bone. The perosteal flaps were sutured over the graft with No. 1 chromic catgut. Three stay sutures were used further to fasten the patellar ligament to the periosteum at a higher level. The medial fascia was then reefed in the upper margin of the patella by means of mattress sutures so that this area had the appearance of a ligamentous support. The skin was closed and a posterior splint of plaster-of-Paris was applied.

Post-operative course. On the second day the temperature rose to 101.6 degrees, it then subsided and ranged around 99 degrees until the eleventh day when it reached normal and remained so thereafter. For the first 3 days he required $\frac{1}{2}$ grain of codeine to relieve the pain; after that no opiates were necessary. On the sixteenth day he was able to walk. On August 7, 1931, he was permitted to return home. One week later he began to walk with the aid of a cane, and gradually began to flex the knee. He bore all his weight on the right limb. The quadriceps power was re-established before full flexion was permitted. He walked up and down stairs one step at a time until the sixth week after the operation. Eight weeks after operation he had full flexion of the knee and apparently normal power of the quadriceps.

The patient has been seen periodically for the past 5 years. At his last visit 3 months ago he had no trouble whatsoever with the knee. There is not the slightest grating, and he is able to run and jump without the least tendency toward any displacement or discomfort. He has absolute confidence that the knee will give him no further trouble in spite of the fact that he had always had a definite feeling of insecurity in regard to the knee from childhood to the time of operation. It is his opinion that the knee operated upon is definitely stronger than the other one.

This patient is an example of a severe congenital anomaly with a slipping patella and a progressive disturbance in function, as well as an increase in the anatomical changes. It is the type of case in which the condition could not conceivably be corrected by any of the previous methods described but it did respond to the procedure used in an entirely satisfactory manner not only from an anatomical but from a physiological standpoint as well.

Fig. 9. Case 2. A Photograph taken after operation. Note that patella is more medial. B Photograph showing patient bearing full weight on leg operated upon with flexion of knee. C, Photograph showing range of flexion. Normal motion was present.

CASE 2 *Recurring dislocation of the patella of congenital origin with loose body in knee joint.*

E. D. (Clinic No. 13240) 27 years of age was admitted to Passavant Memorial Hospital on April 5, 1934, complaining of pain in the right knee the result of locking. Her disability had come on so insidiously that she was unable to set an exact date of her first trouble with the knee, but she had had a feeling of insecurity for the past 13 years. As nearly as she could remember she had had an attack of acute pain in the knee preceded by a locking at the age of 14 years. Six days previous to her entrance into the hospital while waiting upon a customer in a store she suddenly felt something slip in the knee, the knee became acutely painful and began to swell. She was first seen in the office where an x-ray examination revealed a loose body in the knee. Her history was otherwise essentially negative except for a previous pelvic operation (uterine suspension and appendectomy).

Urinalysis was negative. Blood count showed 4,450,000 erythrocytes, 11,940 and 13,300 leucocytes on two occasions, hemoglobin 10.15 grams. X-ray films showed hyper trophic changes in the knee with a large loose body. The bony spine was sharpened and the patella slightly displaced laterally; it appeared to be abnormal in shape.

Under general anesthesia the following operation was carried out:

A curved incision was made starting at the upper margin of the patella along its medial margin down to the tubercle of the tibia. The skin was freed and the patella was exposed; the patella was found to be displaced laterally. The knee was opened on the medial surface and a loose body the size of an almond was removed. Closure in layers was accomplished. The conjoint tendon and the patellar ligament were then exposed. An incision was made along the lateral side of the patella dividing the fascia down to the capsule; this incision was carried up along the side of the conjoint tendon and into the lateral fascia of the vastus muscle. The patella was freed so that it could be drawn easily medially. Then the patella was dissected free and a bony block one half inch square was removed by means of an electrical saw from the tibia in the area of its insertion. The patellar ligament was incised medially about 1 1/2 inches distal to this area. Flaps were thrown back and a bony block about 3/8 inch square was removed. The attachment of the patellar ligament and its block were countersunk in this place. The periosteum was then

sutured over the block. The second graft was fitted into the space of the tibial tubercle. The periosteum was sutured over the graft and re-enforcement sutures were made from the patellar ligament directly to the periosteum of the tibia. The medial fascia was reinforced by reeling at the upper margin of the patella. The skin was closed and a plaster of Paris posterior splint was applied.

Postoperative course. The temperature rose to 100.4 degrees on the tenth day; it was normal and remained so. Sutures were removed on the twelfth day. Recovery was entirely uneventful. The patient was dismissed from the hospital on May 17, 1934. She returned to work in a clothing store on August 1, and was on her feet for 5 hours every day.

She was last seen a month ago. She has had no trouble whatsoever with the knee. She states that the knee operated upon is definitely stronger than the other and that she no longer has any feeling of insecurity, much less any slipping or locking. She has worked continuously. She has noted definite improvement in the appearance of the knee; it is straighter and has what she describes as a more normal appearance. The patella lies in a new position.

This case is an example of a knee that had a true loose body which gave rise to symptoms of which the patient complained at the time of examination. The loose body may or may not have been secondary to her primary condition, which was a congenital type of recurring dislocation of the patella. The anatomical changes consistent with such a diagnosis were very typical in this case. The correction by means of the operation described resulted in complete recovery from all symptoms which dated back to the earliest memories of the patient.

CASE 3 *Traumatic arthritis of the left knee; fracture of the internal semilunar cartilage; slipping patella of the congenital type; genu valgum.*

J. W. DEY (Clinic No. 1059) 20 years of age came for consultation on November 14, 1935, complaining of injury to the right knee. The duration of the trouble was fifteen

Fig 10 Case 3 J W DeV A, Roentgenogram made before operation, showing the loss of joint space and marked swelling of the synovial tissue B, Roentgenogram made after operation The alignment has improved and the swelling of the synovial tissue has disappeared C, D, Photographs showing appearance of the knee after operation

years When she was about 15 years of age, something slipped in her knee while she was walking and she fell The knee was painful and she was in bed 6 weeks Periodically from that time on the knee would suddenly slip out and cause sharp pain Five years previous to examination she stepped off the curb and the knee slipped, causing excruciating pain over the inner side of the knee She was on crutches for several weeks The knee has troubled her ever since and for the past 2 years the pain has been constant She had consulted many physicians and gone to various osteopaths No relief was obtained Casts had been applied with only temporary benefit During this period motion in the knee was practically lost and the knee was constantly swollen Arthrodesis of the knee was advised repeatedly At times the opinion was expressed that it was a tuberculous process, while again no diagnosis was made but still fusion was recommended

At the time of examination there was a marked genu valgum, the knee was so swollen that it was impossible to palpate the patella Motion was painful and the patient was unable to walk without extreme limping and the use of crutches There was some local heat present and tenderness was elicited over the inner side of the knee The x-ray film showed a loss of joint space with signs of arthritis

A diagnosis was made of (1) traumatic arthritis of the left knee, (2) fracture of the internal semilunar cartilage, (3) a slipping patella of the congenital type, and (4) genu valgum

In view of the severe arthritis, a fusion of the knee was justified, but inasmuch as the changes were secondary to a neglected slipping patella with internal derangement of the knee, the patient's desire to avoid the loss of motion at the knee was given consideration, and reconstruction of the knee was agreed upon

The operation was done after the technique described in this thesis It included opening the knee joint to expose the joint surfaces The internal semilunar cartilage was entirely absent There was a membranous tissue over the cartilaginous surface of the tibia The remnants of the semilunar cartilage and its attachment, as well as the membrane were dissected out with a sharp scalpel and

removed The joint surface was then found to be eroded in spots The cartilage was thinner than normal There was an overgrowth of the margin, osteophytic in character, which was removed with a sharp chisel The joint was closed and the technique for repair of the dislocated patella was executed

Postoperative course. The knee showed great swelling on the third day The compression bandage was released and a suture was removed to permit drainage of serosanguineous fluid The swelling gradually subsided and the wound closed In 3 weeks the patient was allowed to go home Eight weeks after operation the motion was limited, and an attempt to gain motion by manipulation under anesthesia was executed An osteoclasis took place at the supracondylar line and the genu valgum was corrected The cast was worn for 5 weeks

When seen 3 months later she walked without the aid of crutches and had no pain The genu valgum had decreased There were only about 10 degrees of motion present, but this was entirely free and painless Motion beyond this point would cause some pain The patient stated, however, that she was slowly gaining more motion in the knee

This case illustrates the damage caused by neglecting a slipping patella over a period of years The recurrent dislocation of the patella in early childhood caused an internal derangement of the knee with probably a fracture of the semilunar cartilage After a period of over 15 years a high degree of arthritis developed A fusion operation seemed indicated and would have been justified In accordance with the patient's request, however, an attempt to correct the condition by means of a total tendon transplant operation was carried out, with a result very satisfactory to her

CASE 4. Traumatic type of slipping patella

I S (Clinic No 12626), 29 years of age, was admitted to Passavant Memorial Hospital on December 26, 1932, complaining of a dislocation of the right knee cap which

FIG. 11. Case 4. I S. A Photograph taken after operation. The knee is able to take full weight bearing with flexion. B Photograph showing the normal appearance of the knee. C Another view. D Roentgenogram made after operation showing patella riding low and in a relatively medial position. The dense shadow in the tibia shows the position of the bone graft with attachment of patellar ligament. E, Another view.

gave rise to pain, occasionally severe, and extreme weakness of the right knee. He stated that 8 years before while playing football he made a quick movement with his right leg and felt a severe acute pain in his right knee. He noticed that the patella was dislocated. He was unable to walk without pain and there was swelling which lasted about 2 weeks. The patella seemed to return to normal position. From that time on, however, whenever he bent his knee the patella would dislocate and at four different times he had severe pain with what seemed like a true dislocation of the knee cap and associated swelling. Past history included measles, mumps and chicken pox and catarrhal jaundice at 14 years of age, otherwise he had always been well.

Physical examination was negative except for the right lower extremity. The right patella was normal in size

and contour. The knee was apparently normal when extended but when flexed there was a prompt dislocation of the patella toward the outside which was not reducible. It was possible to reduce the patella only when the knee was extended. The dislocation occurred each time the knee was flexed. There was definite atrophy of the quadriceps muscle.

Urinalysis was negative. Blood count showed 5,150,000 erythrocytes, 7,500 leucocytes, hemoglobin 16.07 grams.

On December 27, 1932, the following operation was performed:

The patella was exposed through a lateral incision 6 inches long. The fascia on the outer surface of the vastus lateralis was divided as were the ligament and fascia lateral to the patella. These structures were about 1 1/2 inches thick in this area and were firmly contracted. The dissection was carried out until the patella could easily be displaced medially. With the knee flexed, the insertion of the patella was transplanted from its position on the lateral side of the tibia to a point 1 inch medial and 1 inch distal to its former position by means of a bone graft. The new attachment was reinforced with chrome sutures from the patellar ligament to the periosteum. The medial ligament was shortened at the upper margin of the patella. The wound was closed and a plaster of Paris cast was applied.

Postoperative course. The temperature rose to 99.8 degrees after the operation but subsided to normal on the fourth day and remained normal thereafter. Convalescence was entirely uneventful. The patient had practically no pain. The stitches were removed and weight bearing started on the tenth day. The patient walked with the aid of crutches. Motion was started and on the eighteenth day flexion of the knee was permitted. He was dismissed from the hospital on January 14, 1933. Two weeks later he was carrying out his occupation of teaching manual training. The knee gave no pain and its strength increased until its capacity was definitely greater than that of the other knee. He hunted and walked great distances in the fields without becoming tired in the lumbered operated upon. He has had no pain since the operation.

When last seen in December, 1935, he had been playing basketball without the slightest feeling of insecurity concerning his knee. Previous to operation he was unable to drive a car. Since that time he has not only been driving a car but has also taken up aviation. He has never had any concern about a recurrence nor any feeling of insecurity.

This is an excellent example of a recurrent dislocation which had become actually a chronic dislocation. It exemplifies also a true traumatic type of slipping patella. The operation described proved satisfactory in every way and it is difficult to conceive of any other type of operation which would be suitable for the anatomical changes that were present in this case.

SUMMARY AND CONCLUSIONS

1. A classification has been evolved and described on a clinical basis, dividing recurrent dislocations of the patella into three types: (1) congenital, (2) traumatic and (3) rachitic. A description of the anatomical changes in each group is given. The effect of the morbid anatomy is expressed in terms of altered function. The

importance of re-establishment of normal function is emphasized.

2 A review of all the previous operative methods of correction is reported, classifying them into six groups according to the method of attack. This includes a complete review of the literature with bibliography. A critical analysis of each type is made on the basis of criteria set up for a satisfactory operation.

3 An operation is described which is original in that it fulfills all the prerequisites of satisfactory correction, namely: (1) it prevents recurrence of the dislocation (2) it gives the patient a feeling of absolute security, (3) it re-establishes the functional capacity, (4) it gives the knee a normal appearance, (5) the risk to the patient is minimum; and (6) the convalescence is short.

4 The technique of the operation is described in detail, the rationale for each step of the operation is substantiated.

5 Illustrative cases are reported. The method has been in use over a period of 5 years, and the results have been uniformly satisfactory.

SEGMENTAL ENTERITIS

RICHARD LEWISOHN, M D., New York, New York

THE subject of so called regional or, as I prefer to call it, segmental enteritis, is being widely discussed at present. A large number of papers on this subject have appeared in the last 4 years. Opinions differ not only as to the pathogenesis of these interesting lesions but also as to the best method of surgical treatment.

Undoubtedly a few years will elapse until we arrive at fairly definite views concerning the etiology of this disease and the best form of treatment for these lesions.

CLASSIFICATION

While inflammatory tumors of the intestinal tract have been reported for many years, Crohn, Ginzburg, and Oppenheimer (6) first classified these interesting lesions in 1932. Furthermore, they clearly described for the first time the chronic perforations with fistulous communications to other parts of the intestine, that occur mainly in various parts of the colon. Originally they thought that this disease occurred only in the distal 2 or 3 feet of the ileum. For this reason they called it "terminal ileitis." Later observations showed that more proximal parts of the ileum may

be involved. Therefore Crohn adopted the name suggested by Bargen, "regional ileitis."

In 1933 Harris, Bell, and Brunn (9) reported a case in which not only the ileum, but parts of the jejunum were involved. Soon after their publication Crohn (5) stated that he had observed similar cases. He then adopted the name suggested by Brown, "regional enteritis" (7).

Thus in the short period of 2 years it was demonstrated that this inflammatory disease may develop in any part of the small intestine (either jejunum or ileum) and the original name of terminal ileitis had to be changed first to regional ileitis and later to regional enteritis. However, this classification did not completely suffice. A number of those interested in this subject felt that the process was not necessarily confined to the small intestine but might extend (and frequently did extend) into the colon. Colp, in reporting a case of this nature, states: "This case seems to substantiate the belief which many have expressed that regional ileitis is a phase of a chronic inflammatory disease of unknown origin which does not only elect and affect the ileum, but may attack the cecum and other areas of the colon." Evidently this simultaneous involvement of the

From the Surgical Service, Mount Sinai Hospital

Fig 2 Case 2, T W. Resected specimen of segmental ileocolitis

Fig 3 Case 10 G F Resection in 2 stages Primary operation Subacute ileitis with very large mesenteric glands Ileotransverse colostomy

Fig 5 Case 10 G F Barium enema showing extensive ileitis above the ileocolostomy

Fig 4 Case 10 G F Resection in 2 stages Secondary operation Healed ileitis Resection of distal ileum cecum and part of ascending colon

ileum, cecum and colon is not at all infrequent for Brown (2) reported 5 such cases among 18 cases of regional enteritis. In 1936 Crohn (7) reported 9 cases of combined ileitis and colitis. He says "This relationship is usually not sequential

Fig 6 Case 11 D D Resection in 2 stages Specimen of distal ileum cecum and part of ascending colon Healed ileitis

but synchronous. Occasionally, however, it would appear as if a primary ileitis had spread to and involved the colon in a secondary invasion."

It is today a moot question whether the process spreads from the ileum into the colon (Crohn and others) or whether the primary seat in the combined form is in the colon with secondary extension into the ileum (Berg). As long as the cause of this disease is unknown, these opinions are mostly of a speculative nature.

It is evident from this survey that the original conception of Crohn, Ginzburg, and Oppenheimer that this interesting lesion occurs only in the most distal part of the ileum was not correct. Undoubtedly, inflammatory tumors of the intestines occur more frequently in the terminal part of the ileum than in other parts of the intestinal tract. However, they may be and have been observed in any part of the jejunum, ileum, or colon. In fact, similar lesions have been observed in the stomach.

It is interesting to speculate about the cause of the frequency of these lesions in the ileum just proximal to the ileocecal valve. This valve represents the only barrier between the pylorus and the anus. Whether the temporary stagnation of intestinal contents in this region favors the frequency of these inflammatory tumors in the most distal part of the ileum is at present purely problematical.

I doubt whether segmental enteritis represents a clinical entity. As our views on ileitis and ileocolitis stabilize with accumulated experience during the next few years, this lesion may turn out simply to represent a milder form of ulcerative colitis. Many of the cases have a very acute onset with fever, diarrhea, and with mucus and blood in the stools. The cases may belong to a group, in which segmental enteritis represents a lesion caused by a less virulent virus of the same nature which in its more toxic state produces the well known clinical picture of an ulcerative colitis.

Certainly if we compare the picture which Crohn (7) presents of a severe ulcerative colitis (Fig. 1) with the picture of a case of ileocolitis in which I operated upon the patient (Fig. 2), we notice identical lesions in the ascending colon. Both pictures were drawn by the same artist, one from a postmortem specimen, the other from a specimen obtained at operation.

Formerly we considered acute ulcerative colitis as a lesion which always affected the whole colon. In 1930 Bargen and Weber reported a series of cases in which only certain parts of the colon (mainly the transverse or descending colon) were involved in the pathological process. They pointed out the segmental nature of these lesions affecting

parts of the colon, whereas the rest of the large intestine was perfectly normal. These cases represent milder forms of acute ulcerative colitis, whereas the more virulent variety affects the whole colon.

In the same manner ileitis in its most toxic form may affect the whole ileum. Crohn has reported a case in which not only the whole ileum, but the lower part of the jejunum, was involved. Such extensive lesions of the small intestine seem to be extremely rare. However, simultaneous involvement of different segments of the ileum are by no means infrequent. For instance I have noticed in a number of cases that the most distal part of ileum was involved in the lesion. One or 2 feet of ileum above the lesion were perfectly normal. As we inspected the gut farther up, we found another 1 to 2 feet of ileum involved in the same process which was found at the ileocecal valve.

I think the name of *segmental enteritis* indicates very well that in the vast majority of cases this disease is confined to certain well localized segments of the intestinal tract. This general group consists of the following subgroups (in order of their frequency): (1) segmental ileitis; (2) segmental colitis; (3) segmental ileocolitis; (4) segmental jejunitis; (5) segmental jejuno-ileitis.

A very valuable paper has been presented by Erb and Farmer. They reported 4 cases of acute ileocolitis in children and pointed out that the very acute processes which they found mainly in the distal ileum may represent the acute stages of the disease which in its chronic form Crohn and his co-workers have described as regional ileitis. After all, a large number of patients suffering from segmental or regional ileitis or ileocolitis have passed through an acute stage long before they are admitted to the hospital.

Two cases of successful resection for very acute ileitis with gangrene were reported by Jackman. On account of the severity of the symptoms they required immediate operation. With less severe symptoms they might have subsided spontaneously and at a later date presented the familiar picture of a subacute or chronic segmental ileitis.

CLINICAL PICTURE

I shall refrain from discussing in detail the clinical picture of these interesting lesions, as Crohn and his co-workers have given an excellent and minute description of the different phases of the disease in their first publication. I could not add much to the subject. Furthermore Meyer and Rosi and Koster and his associates have covered the same ground. Suffice it to say that the symp-

Fig 3 Case 10 G F Resection in 2 stages Primary operation Subacute ileitis with very large mesenteric glands Ileotransverse colostomy

ileum cecum and colon L. not at all infrequent for Brown (2) reported 5 such cases among 18 cases of regional enteritis. In 1936 Crohn (7) reported 9 cases of combined ileitis and colitis. He says "This relationship is usually not sequential

Fig 6 Case 11 D D Resection in 2 stages Specimen of distal ileum cecum and part of ascending colon Healed ileitis

of the gut in the first free area above the lesion I have noticed in a number of cases that a free area of normal intestine about 1 foot in length existed between two diseased segments. It is clear that unless sidetracking is effected above the lesion, a cure cannot be expected.

Cases 10 and 11 are of sufficient interest to warrant a more detailed description.

CASE 10. G. F. When this patient was operated upon the first time (December, 1935) she presented the typical picture of an ileitis just above the ileocecal valve. The colon was normal. The distal ileum showed an extensive lesion reaching about 3 feet proximally from the ileocecal valve. The first foot proximal to the cecum was markedly involved. Proximal to this lesion there was about 1 foot of gut which seemed to be apparently free from disease and then again we encountered another foot of diseased ileum. The intestine was markedly injected, its wall very much thickened. There was extensive involvement of the mesenteric glands in this area, some of the glands being the size of large grapes (Fig. 3).

In view of this extensive lesion it was deemed advisable to perform an ileotransverse colostomy and to postpone possible resection to a later date.

The patient was observed in the follow-up clinic. After a few months of apparent cure the diarrhea recurred, accompanied by pain in the lower abdomen. It was assumed that the sidetracked distal ileum was still diseased. Removal seemed advisable in order to safeguard the patient against extension of the process into the colon.

At the second operation (June, 1936) the lesion presented an entirely different picture from the lesion encountered at the previous operation. At this time the diseased part presented a small narrowed tube without apparent signs of inflammation. The glands described previously were neither visible nor palpable. We were evidently dealing with a healed ileitis (Fig. 4). Cecum, appendix, and colon were normal. The anastomosis was soft and patent. The excluded part of the distal ileum (2½ feet) was removed with the appendix, cecum, and about 2 inches of the ascending colon.

Pathological report (Doctor Klemperer). The ileum gives the appearance of diffuse atrophy. Its lumen is narrower than normal and it measures 2¾ centimeters in width when opened. In one portion (about 23 centimeters from the ileocecal junction), the width of the small bowel is only 1¾ centimeters. This narrower section extends for a distance of 8 centimeters. The wall of the ileum does not appear to be indurated or thickened. The mucosal surface appears clean and in some areas gives the impression of atrophy. The cecum and resected part of the ascending colon appear normal.

Microscopical report. The mucosa of the terminal ileum is conspicuously narrowed. The glands are widely separated and shortened. The epithelium of the glands consists of cylindrical cells, frequent goblet cells, and Paneth cells. The stratum proprium shows a moderate infiltration of eosinophil polynuclear leucocytes and is chiefly made up of fibroblasts. The submucosa is slightly thicker than normal, made up of connective and fat tissue with areas of fibrosis and contains several lymph follicles. The muscular coat is without changes. The subserosal layer is thickened and shows numerous nodular infiltrations of lymphocytes with sporadic giant cells of the foreign body type.¹

¹This patient was re-admitted in May, 1937. She had been perfectly well up to 3 months ago. Barium enema (Fig. 5) showed an extensive lesion in ileum just above ileocolostomy. Reoperation (July, 1937) showed involvement of about 3 feet of ileum at anastomosis. Resection, cure.

CASE 11. D. D. This patient was first admitted to the gynecological service of the Mount Sinai Hospital in July, 1936, with a 6 weeks' complaint of postprandial lower abdominal pain and vulvar swelling. There was a history of chorea at the age of 5 with 5 annual recurrences thereafter, but no history of cardiac embarrassment. Examination at that time revealed a moderate degree of left cardiac enlargement, a presystolic crescendo murmur, snapping first apical sound, and a soft diastolic apical murmur. A round resistant mass was palpable in the right lower quadrant. On vaginal examination the uterus was found to be normal, but to its right was found a cystic mass. Occupying a semi-circular area to the left of the anus was a reddened nontender, edematous, coxcomb like excrescence made up of three distinct lobules. The right labium majus was twice the size of the left and appeared edematous. The Frei and blood Wassermann reactions were negative. Abdominal exploration disclosed a right dermoid cyst which was resected with the right ovary. The terminal 4 inches of ileum, the cecum, and appendix were found enlarged, their walls thickened and hemorrhagically discolored. A few discrete lymph nodes were found in the adjacent mesentery, one of which was excised for microscopic study and proved to be the seat of a non-specific hyperplasia.

The patient was then transferred to the medical service for further study. A barium enema revealed a stenosing lesion of the terminal 6 inches of ileum and a marked irregular stenosis of the caput coli suggestive of regional ileitis. Agglutination for dysentery was negative. A Rehfuess test meal showed free acid up to 20. A second exploratory laparotomy was then performed on the surgical service. The terminal 6 inches of ileum presented an inflammatory lesion. Two points, one 3 inches from the ileocecal angle and the other approximately 6 inches from the angle, were more extensively involved. Here the induration, redness and narrowing were most severe. The cecum was adherent to the abdominal scar and omentum and therefore could not be visualized. An ileosigmoidostomy with exclusion of the inflamed portion of the intestinal tract was performed. Except for the development of a pneumonic process over the left chest posteriorly, the postoperative course was uneventful and the patient was discharged to the outpatient department on the fourteenth postoperative day, 40 days after admission.

Second admission. The patient was readmitted December 16, 1936, approximately 4 months after her last operation with a history of occasional right-sided abdominal pain, a tender mass in the right lower quadrant, and a recent increase in number of stools.

The additional pertinent physical findings were an irregular, slightly tender mass within the right lower quadrant, enlargement of the right labium majus and a firm perianal mass 1.5 by 0.75 inches. The heart presented the evidence of a chronic valvular lesion described on the first admission. It was feared that in the presence of diarrhea the inflammatory process might extend along the large bowel.

Operation consisted of resection of the distal ileum, cecum, and ascending colon, with closure of fistulous communications between the ileum and transverse colon and between a high loop of ileum and a portion of the non-functioning ileum. Several hours after this operation the patient's respirations increased to 32 per minute and numerous fine basal râles were heard. On the morning following operation, the respiratory rate had risen to 40 per minute. A moderate degree of cyanosis of the lips and nail beds also appeared. A roentgenogram of the chest showed evidence of an extensive bronchopneumonia. The patient's condition rapidly grew worse, her cyanosis increased in intensity, the pulse mounted to 150-170 and became very poor in quality. Her temperature rose to 103.4 degrees, death

toms of fever, diarrhea with mucus and blood in the stool loss of weight and anemia are very similar—though all in an attenuated form—to those which we encounter in acute ulcerative colitis. On the other hand, segmental enteritis presents two outstanding symptoms which we are not apt to find in ulcerative colitis, namely (1) fistulous communications between the lesion and other parts of the intestinal tract, and (2) symptoms of incomplete intestinal obstruction.

However, I would like to point out that perianal fistulas and rectovaginal fistulas are associated occasionally with this disease. They may occur in cases in which the main lesion is confined to the small intestine and in which the colon is absolutely free from disease. It is interesting to point out that in the same way as there may be a connection between terminal ileitis and the ileocecal valve (see above), the anal barrier may favor localization of the virus in this region with *secondary fistula formation*. These fistulas may give an important clue toward establishing the correct diagnosis. For this reason they deserve more attention and more minute consideration than they have received in previous publications on this subject. Three among our 11 cases had inflammatory processes in the anal region, one had multiple fistulas in ano, one had a recto vaginal fistula, one a virgo had condylomas.

This disease seems for the most part to affect persons in the second and third decades. However, cases have been reported, in which the disease occurred in infancy. For instance, Rockey and Meyer have reported cases in children 5 and 9 years old. Among our 12 cases only 3 patients were above 21 years old.

There seems to be no predilection for one sex as compared to the other. Koster states that among 62 cases reported in the literature 33 were males and 29 females. In our material of 12 cases 5 were males and 7 were females.

Crohn (5) has reported the cases of a brother and a sister who had this disease and suggested the name of 'familial ileitis'. He states 'The occurrence may be purely accidental or it may have significance as to a congenital predisposition or a transmissible causative agent in this disease'. In our material, Cases 7 and 9 were sisters, one married, the other unmarried. They had not lived in the same house for many years. I think the occurrence of ileitis among members of same family is, as in many diseases, purely accidental.

SURGICAL TECHNIQUE

Segmental enteritis is a distinctly surgical disease. There are two methods for dealing with

this condition (1) resection in one or two stages (2) sidetracking (ileocolostomy with division of the ileum above the lesion). Before we discuss the comparative values of these procedures I would like to mention that apparent cures have been reported after simple exploration or not more than an appendectomy (Meyer, 3 cases Koster 7 cases). However, the observation time in these cases extended over a few months only. One case only was followed for more than 1 year, and none of the cases for 2 years. It is very probable that these improvements are due to remissions in the disease rather than cures. Crohn has reported a case which 2 years after simple exploration and a gain of 50 pounds required resection due to incomplete intestinal obstruction. Meyer reports a case which 3 weeks after exploration required resection on account of progressive symptoms.

While we can thus dismiss with a few words simple exploration as a non curative and unsurgical procedure we are not prepared at present to state that resection either in one or two stages must be performed in every case in order to effect a cure. We have tried on my service not to be too arbitrary about resection as we have seen cures following simple sidetracking. Sidetracking means a complete division of the small intestine above the lesion closing of both cut ends by a three layer suture to be followed by a lateral anastomosis between the ileum and transverse or descending colon. A lateral anastomosis without division of the intestine is a useless operation as the affected part of the bowel is not put at rest.

It is not the object of this paper to give a detailed description of the operative technique employed in our 12 cases (see Table I). Three patients were subjected to primary resection 4 were resected in two stages whereas in the 5 remaining cases shortcircuiting was done.

One patient (Case 11) died within 24 hours after the operation of an acute rheumatic endocarditis.

With one exception (Case 7) division of the ileum above the lesion with ileocolostomy seems to have effected a complete cure in our series, whenever this simple procedure was employed. In 1 case (Case 4) multiple external fistulas healed completely following this procedure. In another patient (Case 5) an enormous mass (size of a grapefruit) began to shrink in size immediately after the operation and had practically disappeared when the patient left the hospital 3 weeks after the operation.

However as I have pointed out, the segmental character of this lesion must be kept in mind by the surgeon. It is not safe to make the division

ulcerated areas were also found toward the tip. The heart was moderately enlarged for the size of the individual and weighed 240 grams. There was evidence of a chronic rheumatic interstitial valvulitis of the mitral and aortic valves with a recently superimposed verrucous endocarditis of the mitral and tricuspid valves. The lungs were markedly edematous and congested. There were also chronic passive congestion of the spleen and kidneys, a moderate amount of fluid in the peritoneal cavity, a few focal mucosal ulcerations of the transverse colon and the peri-anal inflammatory zones as described clinically.

Cause of death: acute rheumatic valvular disease.
The specimen showed a healed ileitis.

This patient in spite of her heart lesion had stood two previous laparotomies very well. Pulse and temperature were normal. There were no clinical symptoms indicating an acute exacerbation of the chronic rheumatic valvular lesion.

The palpable mass was due, not as we suspected to an inflammatory lesion of the mucosa of the ileum and ascending colon, but to a marked peri-ileitis and pericolicitis, a remnant of the previous acute inflammation. This case demonstrates that a tender mass may be present in the presence of a healed lesion of the intestinal canal.

It will require the combined experience of many surgeons before the question can be answered whether simple sidetracking effects a real cure in a large percentage of the cases. Even at the present time we can state that some cases may be cured by this simple procedure. This observation which has been made by a number of surgeons is of considerable practical importance. In many instances these patients were first operated upon under the erroneous diagnosis of appendicitis. After the abdomen is opened, the true pathology presents itself. The surgeon, especially in small communities, may not want to risk a removal of the lesion, which undoubtedly represents a major surgical procedure. For this reason in many cases the abdomen has been simply closed up or the normal appendix has been removed, with persistence or aggravation of the symptoms. Under circumstances such as described the surgeon, instead of closing the abdominal incision, should perform a sidetracking operation, a comparatively simple procedure. Meyer states: "Shortcircuiting operations reported by Brown, Borgen and Weber (2), Clute, and others have given relief in about 50 per cent of the patients. In the other 50 per cent the pathological process progressed so that resection of the involved bowel became necessary."

It is impossible at present to answer the question whether simple sidetracking operations will affect a permanent cure in a large percentage of the cases or whether primary resection is preferable. In the presence of fistulous communications

with other parts of the intestinal tract which are frequently encountered in this disease primary resection becomes mandatory.

In closing, I would like to state that Crohn, Ginzburg, and Oppenheimer deserve a great deal of credit for having focused attention upon these interesting lesions. These inflammatory lesions which under the name of infective or non-specific granulomas and similar terms were formerly considered surgical rarities seem to be much more frequent than we were led to believe. Before these authors gave us a clear picture, in many cases an exploratory laparotomy led to a diagnosis of inoperable carcinoma or of tuberculosis. While active discussion as to the etiology and classification of these lesions will probably persist for a number of years, the fact has been established definitely that segmental enteritis is a disease which, in a large percentage of cases, can be cured by comparatively simple operative procedures.

CONCLUSIONS

1. Segmental or regional enteritis is not a rare disease.
2. Opinions differ widely not only as to the pathogenesis of these interesting lesions, but also as to the best method of surgical treatment.
3. This lesion is encountered most frequently in the terminal ileum. However, it may occur in any part of the gastro-intestinal tract.
4. It is doubtful whether segmental ileitis and ileocolitis are clinical entities. They may represent an attenuated form of acute ulcerative colitis and ileitis.
5. Perianal fistulas are frequently encountered.
6. Ileocolostomy with division of the ileum may effect a complete cure.
7. In the presence of fistulous communications with other parts of the intestinal tract primary resection becomes mandatory.

TABLE I—REVIEW OF 12 CASES OF SEGMENTAL ENTERITIS

Number Year	Name Age	Hospital number	Previous operations	Clinic laboratory operative findings	Operation	Operation	Follow up 1935
1 1934	N K 21	385390	Appendectomy 1 mo previously at another hospital	Jejunum with partial intestinal obstruction	Lateral anastomosis jejunum ileostomy	Klingenstein	Well for 3 years; no recurrence of symptoms Eploration not used
2 1934	T W 19	375033	None	Ileocolitis	Resection of cecum	Lewisohn	Well. Has gained 4 lbs
3 1935	R K 16	381917	None	Ileitis	Sigmoidectomy ileostomy	Klingenstein	Feels well. Has gained 5 lbs. Occasional diarrhea. Tenderness in right lower quadrant
4 1935	H B 21	384528	Drainage of intra- abdominal abscess at another hospital	Ilitis. Large inflam- matory mass with multiple abdominal tenderness	Sigmoidectomy and transverse colectomy	Ginsburg	Perfectly well. Has gained 40 lbs. Sigmoid completely healed
5 1935	L H 17	385416	None	Large inflammatory mass size of grapefruit in region of cecum	Ileotransverse colectomy	Lewisohn	Mass disappeared completely in 2 weeks Patient perfectly well Has gained 60 lbs
6 1935	H H 19	386437	None	Ileocolitis	1 Sept 1935 Ileostomy 2 Nov 1935 Resection of distal ileum ascend- ing and transverse colon 3 Ileostomy for obstruction 4 Enterorrhaphy for perforated ileum distal to ileostomy tube	Klingenstein	Patient perfectly well. Has gained 15 lbs
7 1935	S A 30	380365	Appendectomy 4 mo previously at another hospital. Secondary ileal fistula	Ilitis	1 9 9 Resection of ileum 3 inches above ileocecal valve. Ileosig- moidectomy 2 Jan 1936 Ileosig- moidectomy 3 Ileocolitis 4 Nov 1936 Resection of ileocecal junction and distal half of transverse colon	Willsky Klingenstein Klingenstein	Considerably improved
8 1936	R M 24	392426	None	Ileocolitis. Sigmoid ileum and ascending colon involved	Resection two-stage	Lewisohn	Perfectly well. Has gained 15 lbs
9 1936	S F 24	393835	None	Ilitis 3 ft. with fistula into sigmoid flexure Rectovaginal fistula	Resection two-stage	Lewisohn	Feels well. Has gained 40 lbs in 3 mos. Plastic for recto- sigmoid fistula to be performed
10 1936	G F 39	394502	None	1 Subacute ileitis with very large mesenteric glands 2 Healed ileitis	1 Ileotransverse colectomy 2 Resection of ileum and cecum	Lewisohn	1937 Recurrence of disease. Ilitis above ileocecal junction Resected. Cured
11 1936	D D 17	396217	July, 1936 resection of right ovary on Gynecological Service due to chronic pelvic inflammatory disease	Aggravated ileitis complicated with peri- ectic inflammation Dec 1936 healed ileitis	1 Ileosigmoidectomy 2 Resection of distal ileum cecum and part of ascending colon Closure of multiple fistulas	Ginsburg Lewisohn	Diet adjusted after operation. No recur- rence of disease
12 1936	A K 15	396446	Exploration 6 weeks previously at another hospital	Ilitis	Ileostomy	Klingenstein	Completely well. Has gained 35 lbs since operation. Occasional bowel movements

occurring approximately 24 hours following her second operation.

Anatomical findings. Surgical specimen consisted of 24 centimeters of ileum appendix and 10 centimeters of cecum and ascending colon. The serosal surface of the ileum was smooth and injected. The mucosa of the proximal 11 centimeters of ileum was granular and congested; that of the distal 13 centimeters of ileum pale and superficially scarred. The wall of this portion gradually increased in

thickness to 5 millimeters toward the ileocecal valve. The mucosa over the ileocecal valve was deeply scarred. Pro-
jecting from this area was a cherry sized polypoid pedunculated mucosal polyp. The mucosa of the cecum and ascending colon was pale, flat and the seat of shallow scars and three scattered small pedunculated polyps. The appendix measured 15 centimeters. The mucosa in its proximal 4 centimeters was granular, edematous, hemorrhagic and ulcerated (Fig. 6). Many flat stellate hemorrhagically

Fig 1 Diagram showing conditions in author's case, true rectal impalement with intraperitoneal involvement. Accident occurred in male child, 11 years of age, and was due to fall on the pointed end of a biliard cue. Laparotomy performed within 4 hours after injury. Recovery following operation.

Fig 2 A, Lenormant's (6) case of rectal impalement with associated bladder perforation. B, Gentil's case (6) of urethral laceration following rectal impalement. C, Ravenel's case (13) of atypical rectal impalement with perforation of both walls of the rectum and both walls of the bladder.

Rouques' case report deals with a patient who had a perforation of the lower pole of the left kidney as well as a laceration of the diaphragm, and Ravenel reports a case of intraperitoneal atypical impalement of both walls of the rectum complicated by perforation of both walls of the urinary bladder (Figs 2, 3, 4).

Van Hook's personal case was an intraperitoneal impalement of the rectum of the true type in a boy of 13 years. The patient was operated upon 24 hours after injury and died of a generalized peritonitis.

The greater part of rectal impalements are produced by a fall on the buttocks or a tumble from a height or an elevated spot, and it is curious to note that the greater percentage of reported cases resulted from a fall from a hay loft on to the handle of a pitch fork.

It can be easily seen that the intrarectal perforation is accomplished with a certain violence, the body weight of the patient coming from a height to impale itself with a definite force. It is, therefore, not astonishing to find that the affecting agents which make these very deep lesions may be the blunt ends of objects.

The perforation of the anterior rectal wall at a rather low point is favored by the oblique relation of the rectal wall axis to the plane of the pelvic outlet. It is for this reason that many

of the injuries caused by impalement are limited in their effect on the pelvic tissues.

The impingement of the penetrating object on the parts immediately supported by the bones, and more especially by the sacral promontory, will often limit the extent of the lesion.

As a rule, in cases in which the peritoneum is not involved, the mortality is negligible, but with intraperitoneal injury mortality rates as high as 71 per cent have been reported.

With regard to the age of occurrence and sex incidence there is little of importance noted in the literature in the reported cases. Forty-seven of the 59 cases reviewed by Van Hook in 1896 were males.

SYMPTOMATOLOGY

The symptoms encountered will depend on the location and on the extent of the perforation and also upon whether or not the peritoneum has been involved.

In the pure type in which the inflicting weapon has entered the anus and thereafter pierced the intestine, there may be no local signs present whatsoever. If the lesion is extraperitoneal, the blow having been deviated by some of the pelvic bony prominences, there may be some local signs of hemorrhage, and by proctoscopy a mucosal tear in the rectal wall may be visualized.

IMPALEMENT OF THE RECTUM

FRANCIS M CONWAY, M D F A C S, New York New York

PERFORATIONS of the rectum by impalement are among the most serious of the unusual accidents necessitating emergency surgical care

That lesions of the rectum acquired in this way have long been objects of study is demonstrated by the various contributions on the subject. A careful historical review of the literature appears in the contributions of Weller Van Hook in 1895 and 1896 and in Quenu's presentations of 1899 and 1900.

In this country Van Hook was the first to review the literature as well as to collect a series of cases. His original article followed his fatal case in 1895, after an intraperitoneal rectal perforation, his young patient succumbed to a generalized peritonitis.

ETIOLOGY

While impalement of the rectum by penetrating bodies has been recorded only infrequently, the occurrence of such lesions is doubtless much greater. The arrangement of the thigh surfaces, of the ischial tuberosities and of the soft parts surrounding the anus have a tendency by their funnel like contour to direct penetrating objects into the rectum.

The morbid anatomy of impaled wounds of the rectum is strongly influenced by the direction in which the object enters the rectum as well as the size and shape of the object. Sharp objects, such as sharpened stakes, picket fences, and handles of pitch forks and goring by horns of animals have been the commonest causes of these injuries in the past. In the case presented herewith, a fall on a billiard stick's pointed end was the impaling implement (Fig 1).

The wounds resulting from this type of injury

fall into two main groups and the prognosis of each type is entirely different.

In the first group, the so called "pure type of impalement, the injury is one in which the piercing object goes directly through the anus, and after passing through the rectum pierces the intestine at a higher level. In other words in this type of accident perforation of the rectum occurs from within the rectum out through the intestinal wall. Fortunately, this is the rarer of the two forms for it is attended with considerable mortality. The case which is detailed in this report is of this type.

The second group which actually comprises the majority of the cases consists of the so called "atypical impalements." Here rectal perforation is secondary to perineal perforation or a wound occurring at some distance from the anal orifice.

The fact that this group comprises the commoner type of injury is probably the reason they are not more frequently detailed. In this variety of lesion the perirectal and pararectal tissues are pierced before the bowel wall itself is perforated. Likewise in this class of injuries there may be either the extraperitoneal or intraperitoneal involvement, depending upon the course of the impaling weapon.

These lesions may become multiple and complicated as when the endopelvic structures with the muscle planes and cellular interstices of the ischio-rectal fossae are involved. Involvement of other viscera with such perforations have been reported, the urinary bladder being the commonest organ affected. Gubal refers to Lenormant's case with a bladder involvement. Gentils case with a urethral laceration. LaMarnere's report of a case with involvement of the adnexa. Bichat and Job's report of 2 cases in which in addition to the large intestinal perforation patients also had wounds of other small intestinal loops (Figs 2 3 4).

TREATMENT

With any sign of intra-abdominal peritoneal involvement, recovery will depend upon early laparotomy with suture of the perforation and drainage.

Prior to operation proctoscopic examination may be of help in those cases in which the impalement is extraperitoneal. For the extraperitoneal and perineal wounds, exploration with incision and packing of the track is urged with symptomatic treatment and careful observation for complicating abscess or fistula formation.

The question of colostomy in an attempt to deviate the fecal stream in those patients with extensive perineal laceration is also a decision that can be made only in each case as such an eventuality arises. In those cases with extensive rectal wall laceration and perineal muscle destruction, this method of aiding healing would seem to be the procedure of choice. It is in such cases that the residual disability often leads to chronic invalidism due to the many pocketings and fistulous tract formation.

CASE REPORT

J. D., a white male child of 11 years, was admitted to the surgical service of the Gouverneur Hospital on August 31, 1936, complaining of generalized lower abdominal pain. Four hours preceding admission the boy was said to have been impaled on the sharp end of a billiard stick after having fallen a distance of several feet.

About 1 hour before entering the hospital he was given a soap suds enema and his parent states that a small amount of blood was found in the return. This measure failed to relieve his pain and he was brought to the hospital for examination. On admission the patient appeared acutely ill and complained of generalized abdominal pain. There was board-like abdominal rigidity which was more marked in the lower abdominal quadrants. His pulse was 110 and his temperature 100. The white blood count was 14,150 with 84 per cent polymorphonuclear leucocytes. A proctoscopic examination was performed but was inconclusive, there being no gross hemorrhage and no visible lacerations in the rectal wall.

Pre-operative diagnosis was that of perforation of the large bowel due to impalement by billiard stick.

At operation, a lower left rectus incision 5 inches in length was made, splitting the muscle. When the peritoneum was opened between clamps considerable grayish seropurulent material oozed forth. With the suction apparatus about 200 cubic centimeters of this turbid fluid was removed from the pelvis.

The small intestinal coils were packed away with warm pads and a few small blood clots were found in the pelvis. The sigmoid and the intra-abdominal portion of the rectum were examined. On the anterior wall of the rectum, at a level with the sacral promontory, there was a longitudinal tear 2 inches in length. The intestine was seized with an Allis clamp at each end of the laceration and several interrupted sutures of No. 1 chromic catgut were placed and tied. A second layer of sutures was placed to infold further the lacerated area and the peritoneal reflection was sutured over the closure.

Two cigarette drains were then placed in the pelvis, one

on each side of the rectum, and brought out through the lower angle of the wound. The abdominal wound was closed in layers down to the drains at the lower angle.

The postoperative course was stormy for the 3 days immediately following operation during which time supportive measures in the form of continuous intravenous saline and glucose were employed. On the fourth day after a spontaneous bowel movement, he was greatly improved and from that time forward his course was one of progressive recovery.

On the thirteenth day following operation a definite fecal discharge was present along the sinus tract at the lower angle of the wound. The discharge continued until the twenty-seventh postoperative day, when the wound ceased to drain.

Shortly before his discharge from the hospital on October 15, 1936, a barium colon enema was performed and the roentgenograph was reported as "revealing the rectum and sigmoid normally outlined. There was no sign of any fistulization, stenosis, or fixation of the rectum. The sigmoid and rectum emptied completely of the opaque mixture thus demonstrating the absence of any mural defect due to the impalement."

He was discharged in excellent general condition 6 weeks after admission with the wound healed firmly.

Follow-up reports have all been satisfactory regarding his general health and bowel habit.

SUMMARY

1. Impalement of the rectum is an unusual surgical emergency demanding immediate attention and care.

2. Two types of impalement are described, the true type and the atypical variety in which the perforation occurs in the adjacent peri-anal region and extends into the rectum.

3. The morbid anatomy of impaled wounds is strongly influenced by the direction in which the object enters the rectum as well as the size and shape of the offending implement.

4. Many injuries due to impalement are limited in extent by the impingement of the penetrating body on the sacral promontory.

5. Of the visceral complications reported with this type of injury, perforations of the bladder are the most common although secondary involvements of the urethra, adnexa, large and small intestine, kidney, and diaphragm have been reported.

6. A case of true rectal impalement due to a billiard stick with intraperitoneal rupture in a child of 11 years is reported with a recovery following operation.

7. Symptomatology will depend upon the location and extent of the impalement and whether the wound is intraperitoneal or extraperitoneal in type.

8. Residual disability in many cases of extraperitoneal wounds of both varieties is due to multiple fistulas and abscess formation and may dispose to chronic invalidism.

Fig 3 A Bichat and Job's case (6) in which in addition to the intraperitoneal rectal impalement there were perforations of the descending colon and several loops of small intestine

With penetration of the ischiorectal fossae there may be fullness in the perineum associated with localized hematoma formation. Later abscess development may lead to more intense pain and bulging with perineal fistulization.

The constitutional effects, at the onset, may be very slight in this form of rectal impalement, but at a later date with abscess or fistula formation they will be those attendant upon sepsis. In the pure type of impalement in which the inflicting weapon penetrates the peritoneum, in addition to perforating the bowel wall, there is a very different clinical picture.

There may be no local signs present in the perineum, and proctoscopic examination may be quite non-informative. With the involvement of the peritoneum, however, all the immediate signs of acute intraperitoneal visceral penetration will be present. Shock, as manifested by rapid pulse, cold clammy skin, pain in the lower abdominal quadrants associated with localized tenderness and increased muscular rigidity are present. There are also the attendant signs of an acute spreading generalized peritonitis. This type of injury is of a much more serious import and carries with it an exceedingly high mortality owing to the rapidly spreading peritonitis.

In the case reported in this article the tip of the billiard cue entered the anus and perforated the superior anterior surface of the rectum just below the sacral promontory. The laceration which measured 2 inches in length was found

Fig 4 LaMarnière's case (6) of associated laceration of the adnexa with impalement of the rectum. B Rouques case (14) of rectal impalement in which in addition to a laceration of the lower pole of the left kidney there was a perforation of the left dome of the diaphragm

deep in the true pelvis of this young patient. In addition, an acute spreading peritonitis was present at the time of operation some 4 hours after the accident (Fig 1).

Proctoscopic examination prior to operation disclosed no laceration of the mucosa of the rectum and there was no bleeding by rectum.

In contradistinction to the true type of rectal impalement are both the local and the constitutional signs attendant upon the atypical case without intraperitoneal penetration. As a general rule most of the atypical lesions are extraperitoneal although it is evident that there may also be intraperitoneal involvement. When the original site of perforation is a distance from the anus the bleeding may be quite profuse owing to the vascularity of the perineum.

Local laceration, fullness, pararectal tenderness due to hematoma are all common local findings reported in this variety of injury.

PROGNOSIS

It is obvious that the prognosis in both types of injury will depend upon the gravity of the anorectal lesion, the ramifications of the path of injury, and the attendant complications, such as peritoneal or other visceral perforations.

EVIPAL SOLUBLE: BASAL ANESTHESIA

M L WEINSTEIN, M D , Chicago, Illinois

SINCE anesthesia is rapidly becoming selective, with the trend definitely toward basal anesthesia, we are reporting herein our preliminary experience with the colonic administration of a non-volatile narcotizing agent. Rectal anesthesia is not a new procedure as evidenced by the report of Roux, who in 1847 described the administration of an ether water mixture into the rectum with view to the production of complete surgical anesthesia. In the same year the method of Roux was somewhat modified by Megendie in that he substituted ether vapor for the hydro-ether solution. Neither of these procedures gained in popularity, due to cumbersome apparatus employed and the varying degrees of anesthesia obtained. The status of colonic anesthesia remained stationary until 1884 when Mollerie suggested the administration of ether vapor into the rectum by a hand bellows and subsequent supplemental anesthesia by inhalation. This perhaps is the first record we have of basal anesthesia by the colonic route. Following the report of Mollerie, Wier and Bull published independently concerning their experience with rectal etherization and at the same time called attention to the grave dangers encountered with colonic ether. Other observers extended the original work and confirmed the previous observations, and a number of articles appeared in the press indicating that the methods of administration employed were entirely unsatisfactory since it was impossible to control the stages of anesthesia by measuring the volume of ether vapor administered. Furthermore, frequent reference was made to the high incidence of rectal irritation due to the anesthetizing agent. These observations no doubt served to discourage rectal anesthesia which fell into disuse until 1902, when Cunningham and Lahey (3) reported the successful use of an apparatus designed for the introduction of ether laden air into the rectum. This method of anesthesia presented distinct advantages over the former comparatively crude methods and received wide recognition by numerous anesthetists. In 1910 Sutton constructed a modification of the Cunningham (2) apparatus which permitted the intrarectal administration of ether vapor and oxygen. This procedure was successful but soon fell by the wayside because of the complicated

apparatus and frequent unpleasant by-effects. The next most noteworthy advance in colonic anesthesia was made by Gwathmey, who in 1913 completely described the technique and safety of his well known method before the International Medical Congress in London. Later, in 1915, he published a complete survey of the subject in the *American Yearbook of Anesthesia and Analgesia*.

Gwathmey's method of rectal anesthesia has been used throughout the world and remained without competition until 1927 when Eichols introduced avertin (tribromethanol). The advent of avertin presented numerous advantages over ether since it was possible to calculate the required dosage according to the patient's body weight. Avertin was first employed as a crystalline salt in doses of 120 to 140 milligrams per kilogram of body weight. These doses were necessary in many individuals to obtain complete anesthesia, but today are rarely employed since they are not without danger because of the extreme depression occasionally encountered. Further research with avertin by numerous investigators has popularized it as a basal anesthetic possessing a satisfactory margin of safety when employed in doses of 60 milligrams to 80 milligrams per kilogram of body weight. As with all other anesthetic agents, avertin too has its disadvantages which in the main are: a relatively large volume of fluid, the extreme care necessary in the preparation of solution, the possibility of chemical decomposition due to heat.

In 1936, Gwathmey again revived rectal anesthesia when he reported his experience with the intrarectal administration of a 10 per cent solution of evipal soluble. Here again the dosage is based directly upon the patient's body weight (10 cubic centimeters of a 10 per cent solution for every 50 pounds body weight). In discussing his 150 cases, Gwathmey indicates that the technique employed is simpler and easier than that required for ether and oil by rectum and that evipal soluble is a safe and satisfactory pre-anesthetic medication.

Evipal soluble is a water soluble derivative of barbituric acid known chemically as N-methyl cyclophenyl-methyl malonyl urea. According to Maloney and Hertz, it exhibits a rapid and high hypnotic co-efficient and a very short duration of action, with a toxicity considerably lower than that of other so called short acting barbiturates.

From the Chicago Memorial Hospital

9 Treatment will vary with the individual case but will be determined essentially by whether or not there is peritoneal or other visceral involvement. In extraperitoneal impalements in which there is extensive perineal laceration, the use of colostomy has aided healing immeasurably by allowing the divergence of the fecal current from above.

10 The mortality in these cases is exceedingly high with the intraperitoneal involvement. In some series more than a 71 per cent mortality occurred.

basal anesthetics, however, the degree of anesthesia and analgesia is very light and is not suitable for surgical procedures. Amentia is always present

Whether the patient is asleep or in the state of seminarcois, supplemental anesthesia is necessary to complete narcosis for a major procedure. We have utilized inhalation, local, caudal, and spinal, and in several instances the pre-anesthetic narcosis was of sufficient depth to permit minor surgery.

A review of the 60 cases presented in this series would indicate that in no instance was there evidence of idiosyncrasy to the drug. This is particularly significant when consideration is given to the variance in the age, weight, and general condition of the patients. The age incidence varied from 9 to 82 years, while the weight varied from 66 to 175 pounds. Generally speaking, the entire group presented a satisfactory risk from a surgical standpoint. A perusal of Table II will indicate the procedures we have attempted under this type of anesthesia.

In these cases we were particularly impressed with the relaxation and reactivity of the patient. Preliminary medication consisted of 1/48 to 1/20 grain of dilaudid parenterally (see dosage table), however, in 3 cases a barbiturate was substituted for the opiate. The latter procedure is not recommended since it almost invariably leads to a confusing clinical picture and frequently results in a prolonged narcosis. The dosage of evipal soluble ranged from 1 to 3 grams, being individualized in each instance in accordance with the age, weight, and general condition of the patient. We purposely varied the type of supplemental anesthesia, as shown in Table III. In 4 cases, however, supplemental anesthesia was not required.

TABLE IV.—DOSAGE

Weight pounds	Evipal soluble		Premedication (parenterally) Dilaudid—grains
	Grams	Grains	
45 to 60	0.6	10	1/40
60 to 75	1.0	15	1/40
80 to 95	1.3	20	1/30
100 to 115	1.6	25	1/30
120 to 135	2.0	30	1/20
135 to 150	2.6	40	1/20
155 to 175	3.0	45	1/20

The dilaudid is given hypodermatically 1/2 hour prior to the intrarectal administration of the evipal soluble solution, which is prepared according to the above dosage scheme. The required amount of evipal soluble is dissolved in 30 cubic centimeters of distilled water and instilled into the rectum about 20 minutes before operation.

The average variation in blood pressure was a drop to the extent of 10 to 30 millimeters of mercury. In several cases the pressure was unaffected, while in 2 instances there was a slight increase following the completion of the surgical procedure. Relaxation was generally good and was comparable to that obtained with spinal anesthesia. The respiratory rate showed little deviation from the normal except in two instances, in which it dropped as low as 10 per minute. A postoperative sleep closely resembling the normal was observed to last from 1/2 to 6 hours.

In 2 instances there was a cyanosis of mild degree which cleared up rapidly following the administration of carbon dioxide and oxygen. One patient was a female, 82 years of age, with a fractured femur and a co-existing myocarditis, to whom we administered 1/20 grain dilaudid and 2 grams evipal soluble. A reduction was accomplished under this medication without the usual supplemental anesthesia. The other patient who showed signs of cyanosis was a 31 year old individual with a massive fibroid uteri, to whom 1 1/2 grains of nembutal was given 8 hours prior to the administration of 2 grams of evipal soluble, supplemented with ethylene.

Two deaths occurred in the series, one being a patient with a suppurative appendicitis who died on the ninth postoperative day from a pulmonary embolus. The other individual, who was transfused subsequent to a prostatectomy, expired following an anuria of 7 days' duration caused by

TABLE I—TOXICITY OF BARBITURATES GIVEN INTRAPERITONEALLY

Drug	Mgm. Kilo Minimal anesthetic	Mgm. Kilo Minimal lethal	Therapeutic index
Evipal soluble	25	100	4
Pentobarbital sodium	50	110	2.2
Amytal sodium	80	130	1.6
Barbital sodium	140	450	3.2

eg., nembutal, pernocton, and amytal. Weese has demonstrated that the narcotic dose approaches the hypnotic dose but does not approximate the lethal dose, in dogs the minimal hypnotic dose being 0.026 gram, the minimal narcotic dose 0.030 gram, while the lethal dose is represented as 0.100 gram per kilogram. These figures indicate that the drug primarily affects the sensory and reflex centers in small doses and that the vital centers are unaffected except by comparatively large amounts of the drug. Table I which is taken from the report of Findlay and Findlay indicates the comparative toxicity of barbiturates when given intraperitoneally to rats. Werner and Tatum classify evipal and pentothal as ultra short acting barbiturates.

Numerous investigators have demonstrated that intentional lethal doses of evipal soluble to animals result in death due to respiratory rather than cardiac failure. The liver apparently plays an important part in the rapid detoxication process.

Probably the greatest tribute to evipal soluble lies in the vast number of reports that have appeared in the recent literature concerning its intravenous use as a general anesthetic. In reviewing his 1000 cases, McNelis reports that he has not encountered any alarming symptoms although his patients' ages ranged from 4 to 82 years. In 1 instance he gave a robust patient a total of 40 cubic centimeters of a 10 per cent solution intravenously during an orthopedic procedure which lasted 1 hour.

The intravenous dose of evipal soluble is strictly individualized and is governed according to the reactivity of the patient. The anesthesia produced is rapid, quiet, and of sufficient depth to permit surgical procedures that do not require more than 10 to 20 minutes. Complete recovery is made within at least 30 minutes unattended by nausea, vomiting or excitement. The voluminous reports relative to the intravenous use of evipal soluble are laudatory and indicate that it is a suitable agent for the production of short anesthesia.

Our experience with evipal soluble intravenously has been so satisfactory that we were prompted to employ it rectally after reading Gwathmey's report of its use as a basal anesthetic. The basal anesthetic dose intrarectally, as one would expect, is considerably greater than the intravenous anesthetic dose. Gwathmey uses 0.2 cubic centimeter of a 10 per cent solution per pound of body weight, as an index, that is, a patient weighing 150 pounds would receive 30 cubic centimeters (0.2 X 150). We have from time to time modified this dosage scheme and a review of the cases reveals that we have been prone to effect a slight reduction. A perusal of the accompanying chart will indicate our exploration of minimal and maximal quantities in an attempt to stabilize our dosage. At this writing, however, we are of the opinion that the original dosage scheme suggested by Gwathmey is well within the limits of safety and will produce the desired degree of semiconsciousness in the majority of cases. However, we are inclined to modify the dosage (Table IV). A young robust alcoholic generally requires more than the calculated amount, while anemic, cachectic, and aged individuals usually require only a fraction thereof. Furthermore we feel that allowance should be made for patients who are extremely overweight and in such instances we calculated our dose as the patient's normal weight for his height and age.

The technique of basal anesthesia with evipal soluble is simple. The patient is usually prepared in the customary manner the night before the operation by the administration of the usual sedatives. We prefer luminal in doses of 156 grains or, in extremely nervous individuals we resort to the more powerful narcotics. The next morning the patient is given 1/30 to 1/20 grain of dilaudid 30 to 40 minutes prior to the administration of the evipal soluble solution. The latter is given to the patient in his own room in the simplest manner possible—we employ a milk catheter attached to a glass funnel. From 10 to 15 minutes after the instillation of the evipal soluble the patient is generally asleep and can be transported to the operating room. In some cases particularly when the dose is below a minimal value sleep does not follow in the usual manner and it is necessary to resort to supplemental anesthesia with the patient in a semiconscious state. This has been encountered several times in our series, and it is interesting to note that the patients have no recollection of the previous procedures upon recovery. The sleep produced by evipal soluble is smooth and more closely resembles the normal than that produced by other

The dilaudid is given hypodermatically 1/2 hour prior to the intrathecal administration of the evipal soluble solution, which is prepared according to the above dosage scheme. The required amount of evipal soluble is dissolved in 30 cubic centimeters of distilled water and instilled into the rectum about 20 minutes before operation.

The average variation in blood pressure was a drop to the extent of 10 to 30 millimeters of mercury. In several cases the pressure was unaffected, while in 2 instances there was a slight increase following the completion of the surgical procedure. Relaxation was generally good and was comparable to that obtained with spinal anesthesia. The respiratory rate showed little deviation from the normal except in two instances, in which it dropped as low as 10 per minute. A postoperative sleep closely resembling the normal was observed to last from 1/2 to 6 hours.

In 2 instances there was a cyanosis of mild degree which cleared up rapidly following the administration of carbon dioxide and oxygen. One patient was a female, 82 years of age, with a fractured femur and a co-existing myocarditis, to whom we administered 1/20 grain dilaudid and 2 grams evipal soluble. A reduction was accomplished under this medication without the usual supplemental anesthesia. The other patient who showed signs of cyanosis was a 31 year old individual with a massive fibroid uteri, to whom 1 1/2 grains of nembutal was given 8 hours prior to the administration of 2 grams of evipal soluble, supplemented with ethylene.

Two deaths occurred in the series, one being a patient with a suppurative appendicitis who died on the ninth postoperative day from a pulmonary embolus. The other individual, who was transfused subsequent to a prostatectomy, expired following an anuria of 7 days' duration caused by

the occlusion of the tubules with acid hematin and hemoglobin. Obviously, neither of these fatalities could be directly attributed to the anesthetic.

SUMMARY

1 Basal anesthesia is a rational procedure based upon well established principles.

2 Evipal soluble intrarectally in the proper dosage gives consistently good results as a basal anesthetic when all influencing factors are concerned.

3 The use of evipal soluble according to the method described herein allays the apprehension and fear of anesthesia and predisposes to a much better postoperative course.

4 Pre anesthetic medication with evipal soluble by rectum markedly reduces the normally required volume of supplemental anesthesia by at least 50 per cent.

5 When used in selective doses, the intrarectal

administration of evipal soluble produces a minimal effect upon the respiratory rate, pulse, blood pressure, and body temperature.

6 The results obtained justify its use since it is of distinct aid to the surgeon and anesthetist and contributes to the well being of the patient.

PILONIDAL CYSTS

STEPHEN A. ZIEMAN, M A., M D, Chicago, Illinois

PILONIDAL cysts are by no means rare. In a general hospital, this affection may run as high as 12 per cent of the total admissions (4, 6). Of the 2,515 new surgical cases admitted to the Rush Medical College Dispensary during the past 11 months, 6 cases of pilonidal cysts were found. In the author's series of 3 years' duration, 10 patients have been treated; 6 were men and 4 were women. Rogers (22) at the Massachusetts General Hospital compiled an 8 year summary of 119 cases, 94 of which were males. This high preponderance of males is likewise substantiated in the literature, where 75 per cent of the occurrences have been reported in men (20).

The condition appears to be an affection found principally in stout, well nourished, hairy individuals between the ages of puberty and the late thirties. The youngest patient treated by me was 17 years, while the oldest was 35. All these patients fitted in perfectly with this general description of physical well-being.

Pilonidal cysts may be defined as a congenital anomaly of the sacrococcygeal midline area, characterized by a dimpling pinhole deformity, and apparently unnoticed unless inflamed or discharging an offensive material. The lesion consists of a cyst or sinus tract lined with stratified squamous epithelium and frequently containing hair. The finding of hair may be considered pathognomonic (1). There has arisen, consequently, the various terms associated with this disease, such as pilous cyst, sacrococcygeal cyst, fistula or dermoid, coccygeal cysts, or the present title, pilonidal cyst, a nest of hair. The cases I am reporting answer the description of these terms, 3 of which, however, contained no hair. The remainder all had definite sinus tracts, while one presented a large abscess with cyst formation. In spite of the position of these fistulas, none has ever been reported to have definite connection with the rectum. They have been many times, unfortunately, wrongly diagnosed as rectal fistulas, anal fistulas, ischio-rectal abscesses, and the like.

Numerous theories have been proposed in explanation of the *etiology* and *pathology* of pilonidal cysts. The general finding of hair led to the suggestion that the condition arose from inversion of hair follicles diverted from their normal direction

by some external cause. This ectodermal invagination with arborization (Fig. 1a) has found a number of recent adherents (28, 9). The second theory has as its principal tenet the anomaly of imperfect union of the two halves of the body, thus forming anywhere from a completely cut-off, rolled-over, hollow tube of ectoderm lying subcutaneously (Fig. 1b and c) to almost an entire lack of fusion (14, 2). Third, some (15, 19) considered the condition consequent to an overgrowth of skin during the formation of the nates. It has been suggested that overgrowth of the mesoblast between skin and bone produced an exaggerated dimple. This dimple might lead to a cyst formation by closure at its mouth; or sinus formation, because of attachment and elongation encountered in the rapid growth of bone as compared with skin. Thus the cystic walls might be pulled forward and caudally into a sinus tract.

Lastly, the neural theory considers the cyst formation as an anlage of the development of the neural canal. This was one of the earliest theories proposed, and, with modifications, has many sponsors (5, 27, 16, 10). Just posterior to the primitive groove, the ectoderm thickens, forming the two neural folds. These folds meet in the midline progressing forward and backward. As they reach the most posterior point, they cone outwardly, producing a broad wide opening for the neural groove. Normally, the neural groove closes tightly at the end of the sixth month. In some few cases, however, it remains more or less patent, and there result malformations such as spina bifida occulta (26, 25) (Fig. 2), externa, and the like. In as far as the area is adjacent and adherent to the bony structure of the body, the formation of a sinus tract can readily be understood, the bony parts growing more rapidly than the skin, and if there is attachment to either, the ectodermal rests become stretched into a sinus tract.

As the neural folds coalesce in this region and pinch off from the overlying ectoderm to form the neural cord and canal, ectoderm (Fig. 3) may remain behind, and even a completely well formed continuous sinus tract. This tract may be closed at one or both ends. Consequently, there results a simple isolated cyst, a sinus closed at one end, or one opened at either end, or one even communicating with the spinal canal. A case of

From the Department of Surgery, Rush Medical College

this description is the suggestion for the present paper. Moreover, there has been recorded neural buds in some of the pathological specimens (11), while meningitis originating from an infected pilonidal cyst has been reported by Moise and Ripley and Thompson. Weeder has observed spinal fluid to escape during the excision of a cystic tract.

Subjectively pilonidal cysts are without symptoms unless infection sets in with the usual sequelae of inflammation. There is then swelling, pain over the coccyx with or without abscess formation around the midline or near either buttock. A discharge may be present consisting of sebaceous material and epithelial debris. This sometimes irritates and produces a pruritus. On the other hand, what the patient considers a pimple or an infected blackhead is the usual first symptom to direct his attention to these parts. Why these complaints, however, should only manifest themselves after puberty is a matter of speculation. Some (7) maintain trauma responsible. If we restrict trauma to accidental injury, then it is not likely that trauma as such, plays a large rôle in the etiology of pilonidal cysts. But in the light of abuse created by pressure, forceful sitting down and the many similar acts done unnoticed during the day, along with the irritation occasioned by the presence of encapsulated hair, then most likely trauma is the principal exciting cause.

As to pathology, pilonidal cysts are formed of stratified squamous epithelium lining the cyst or sinus. If a sinus tract is present the epithelium branches thus producing an arborization. These sinuses may be single with one external opening or many, or the sinus may extend unilaterally, bilaterally, up into the groin (3) or down into the leg. Inwardly the sinus may communicate with the prevertebral fascia, extend directly through and into the vertebral canal, even become continuous with the perosteum, the dural linings (18), or arachnoid.

Besides sweat glands, hair follicles, and hair in the cyst, neural buds (12) with end of nerve tissue have been reported, and observed in pathological sections. Assuredly these latter findings speak in favor of a neurogenic origin. Never has any communication disclosed a connection of the tissue tracts with the rectum, nor has any endodermal tissue been observed in their makeup. The usual laboratory tissue report reveals the presence of such tissue structures as skin, subcutaneous fibrous tissue and muscle, all demonstrating the characteristic findings of chronic inflammation.

The diagnosis of pilonidal cyst is usually made from description of the affection and symptoms

related by the patient. Where there is abscess formation, the diagnosis offers some difficulty. Then the condition may be confused with the differentiating diseases associated with perirectal pathology. By way of illustration, I wish to report a case demonstrating the point in question.

E. L. a young man aged 31 years, complained of an intense itching about the anus. There was some moisture present which caused considerable distress owing to its odor and irritation. The patient athletically active felt himself handicapped and thought by shaving he could keep the parts clean and less worrisome. There shortly developed a swelling over his right gluteal region which he attributed to an infected pimple. Conditions became worse forcing him to seek medical attention. The diagnosis of a rectal fistula with abscess formation resulted in an incision and drainage operation. The patient improved temporarily but soon was forced to undergo a repeated incision operation with equally bad end results. Drainage continued over a period of 3 years and was present when the patient came under my care. The gross pathology resembled very closely a rectal fistula and an excision operation was advised. On the operating table however after the injection of methylene blue hydrogen peroxide solution into the old operative wound no communication of the tract with the rectal mucosa could be seen. Dissection of the abscessed area led to the discovery of a double sinus tract extending from several inches on the right buttock to the median raphe and across to the opposite side about 1 inch (Fig. 4). As the fistula crossed the midline an offshoot was directed posteriorly into a large cystic sac approximately 6 centimeters by 4 centimeters lying to the right of the coccyx bone. This cyst was dissected out and its most anterior end terminated in between the sacro-coccygeal articulation. Disarticulation of the joint revealed that the lining of the cyst was in direct communication with the inner vertebral lining of the sacral body and continuous with the inner spinal canal coverings all of which were clamped off as high as possible ligated excised and allowed to retract inwardly. The coccyx being released the perineal rent was closed with plain catgut stitches. An iodoform vaseline pack placed in the dissected area permitted the wound to heal without suture. The patient has had approximately a 5 years freedom from symptoms and objectively no evidence of recurrence.

TREATMENT

There is considerable discussion regarding the treatment of pilonidal cysts. Summarily, the many methods may be condensed to 1, primary closure with suture (8) after excision of tract; 2, flap transplantation (Lahey method, 13); 3, excision with or without the use of the cautery knife (23) and packing. A recent article (8) sponsors the primary suture method, while another (24) leads one to believe that this sort of operation may be performed under the ordinary conditions of office practice. In the light of the above case report it is difficult to conceive how one can consider the treatment of pilonidal cyst a routine office procedure. No one can predict the extent, direction or involvement of adjacent structures of these sinus tracts, and conse-

Fig 1 a, Ectodermal invagination and sinus tract formation with arborization b, Defect formed by imperfect union of the two halves of the body c, The two halves of the body perfectly fused, while the roll of ectoderm, as in b, is cut off, lying subcutaneously as a hollow tube or sinus tract

quently, it appears to be as rash to perform an excision of a pilonidal sinus in the office as it is to resort to an equally dangerous practice of injecting with sclerosing material. Surgeons are unanimous in claiming that primary closure never should be done in recurrent cases, nor in the presence of apparent inflammation. Under these conditions, there is no election, excision and packing is the operation of choice. However, it is my belief that careful dissection can be done only under a general anesthetic with preparation commensurate with the uncertainty apparent in the handling of this type of case.

Excision with the cautery knife and cauterization of the epithelial sinus tract are likewise fraught with several dangers, not the least of which is the collection of serum that follows a burn. Primary closure, consequently, under these conditions appears contra-indicated.

Finally, the method of excision with open pack and permitting granulation from below is time tried, and, in our hands, 100 per cent effective. The objection of long debilitation following such operation with protracted stay in the hospital

Fig 2 The neural folds in the process of fusing. Arrestment in any stage may produce abnormalities, as spina bifida

and subsequent dressings is not substantiated in fact, nor is the criticism of a resulting large tender scar. The average days in the hospital for the writer's series of cases have been 2, while the

Fig 3 Neural folds in process of producing canal and cord a, Cross-section of early stage b, Partial fusion of the two folds of ectoderm c, Cord completed. Retraction of cord from overlying ectoderm, with ectodermal islets pinched off and lying subcutaneously

Fig 4 Illustration of an unusual sinus tract found at operation a Tract with cystic portion completely dissected b Ligation of proximal portion of sinus tract at its exit through sacro-coccygeal articulation c Appearance of field after excision of tract

subsequent period of dressing has extended from 6 to 12 weeks a favorable comparison with the other methods. Nor is the patient restricted from work longer than 1 week. An interesting observation is that wide excision in this region is associated with very little pain or discomfort. But even if there were as much pain as one might believe, the extremely low recurrence should offset any of the above objections. Success is judged by the ultimate criterion of recurrence assuredly, then, the last method is by far the one of choice.

Operative procedure. The procedure followed by the author in pilonidal cyst excision consists in the administration of a gas anesthetic while the patient is flat on his stomach. The usual sterile preparation of the operative field having been

completed injection of methylene blue hydrogen peroxide into the sinus opening is done. We prefer hydrogen peroxide to ethereal mixtures, or simple water in as far as the ethereal mixtures are fat solvents and may lead to spurious tract excursions, while the plain water has very little penetration power. Wide excision of approximately 2 inches on each side of the midline is then done and ligation of the bleeding points accomplished by double No. 0 plain catgut. Occasionally curettage of the pre-sacral fascia is required. With this sacrifice of tissue one is not likely to overlook a remnant of epithelial structure. On the other hand wide excision gives us a large area for complete inspection. On one occasion in spite of such wide excision, the knife dissected a small remnant of sinus tract extending upward toward the small

of the back. Assuredly this extension would have been missed had not such a radical excision been performed. An iodoform pack is allowed to remain in the defect for a period of 24 hours. Thereafter, simple vaseline gauze and mercurochrome constitute the biweekly dressings. At each dressing, the small bands of adhesions across the midline are ruthlessly destroyed, and the wound permitted to granulate, filling in from below only.

SUMMARY

Herein is presented a perspective of the literature on pilonidal cysts, including a summary of the more tenable theories as to etiology.

The pathology and diagnosis are discussed, as likewise a review of the methods employed in treating the condition.

The author finally describes a rare case of pilonidal cyst with sinus tract in direct communication with the linings of the sacral vertebral canal.

THROMBOPHLEBITIS OF VARICOSE VEINS

EDWARD A EDWARDS M D Boston Massachusetts

THROMBOPHLEBITIS is a common condition occurring at some time in the course of about one half of all patients with varicose veins. It is a troublesome, usually painful, rarely a fatal condition. This paper will attempt to show that in spite of the customary cautious attitude which exists among most physicians active treatment of the underlying cause, namely the varices gives quick relief and is not dangerous.

Warnings against active treatment of the varices and the phlebitis are directed mainly against the use of sclerosing injections or operation during the presence of an active phlebitis (5, 16, 4, 27, 35, 25, 12). Several of the writers go so far as to prohibit injections until 6 months, 12 months, or even 2 years have elapsed after the acute attack.

ETIOLOGY

One gathers from the quoted writings that the avoidance of active treatment is based upon the presence of bacteria in the phlebitic veins. The proposition, however, that bacteria are present within the thrombus or the inflamed vein while tacitly accepted, has not yet been proved.

At the outset, the author should like to state that clinically the acute inflammation of phlebitis resembles that of infectious processes and it may be that future work will demonstrate microorganisms responsible for this process. At the present time, however, all the available facts point to the absence of pathogenic bacteria. This thesis has been more fully developed elsewhere (8). Briefly, the evidence against the presence of bacteria are:

- 1 The inability to find them by stain or culture
- 2 The fact that lung infarcts which follow embolism from this source do not go on to abscess formation
- 3 The usual absence of acute inflammatory exudate in the wall of the involved vein or in the regional lymph nodes
- 4 The non involvement of surrounding tissue except in the unusual form of ulcerating phlebitis of the foot described below

5 The fact that operative procedures on the vein including even curettage do not result in sepsis,

6 The presence of thrombogenic factors other than infection, in varicose veins which could by themselves produce a primary thrombosis, and to which the phlebitis could be secondary.

This latter point has not been sufficiently developed, but several factors have been established. They may be grouped into three classes: slowing of the blood stream, physical and chemical changes of the blood, changes in the vessel lining.

Slowing of the blood stream This has been shown by the work of Virchow and latterly by Aschoff to be the most important single factor in producing a thrombosis. It can hardly be doubted that the flow is indeed sluggish in the large sacculculi which constitute varicose veins. This has been demonstrated to the author's satisfaction by the visualization of the venous blood in performing vasography. McPheeters, using this method has published excellent demonstrations of this same fact (22). In his plates may be seen small masses of injected lipiodol floating around within the varices with almost no progressive movement.

The tortuous course of the varices and the presence of outpocketings furthermore produce whorls in the circulating blood. Whorls have been shown to facilitate the deposition of platelets which start the thrombosis (1).

Physical and chemical changes of the blood The cyanosis of a varicose extremity is a good indication of the diminished oxygenation, and deTakats and others (6) indeed found the carbon dioxide content of the blood in varices to be increased above that of the arm veins. This anoxemia is produced first by the stagnation of the blood and secondly by the fact that in severe varices the blood runs downward in the saphenous from the femoral vein. It is thus so to speak supernaturated blood. An increase in carbon dioxide content is said to enable blood to clot more easily, perhaps by increasing its calcium content.

The viscosity and protein content of the contained blood is also increased. An increased viscosity allows easier agglutination of cellular elements. The increase in protein is not wholly due to mere blood concentration as its rise is proportionately higher than the concentration and

the three constituent proteins, albumin, globulin, and fibrinogen, are not always in consistent ratio (28). Since intravascular clotting has been produced by injections of proteins (29), this increase in proteins may predispose to thrombosis in the varices.

The sedimentation rate in venous stasis is increased, probably due to the increase in fibrinogen and globulin (17, 28). This increased capability of the red cells to settle down would increase the chances for the production of propagated thrombi.

Changes in the vessel lining. These are of two kinds, functional and organic. The functional refer to poor nutrition of the venous endothelium and this is occasioned by diminished oxygenation of the tissues. DeTakats and others (6) have demonstrated this poor oxygenation in showing first that the blood which actually bathes the endothelium within the vein is poorer than usual in oxygen content, and secondly that the arteriolar circulation of the limb, as measured by the histamine reaction, is somewhat diminished.¹

The organic changes in varicose veins are numerous, but it is probably far-fetched to ascribe any thrombogenic influence to any but the

intimal pathology. Here are found changes similar to those well recognized as causing thrombosis in arteries, namely intimal proliferation, vacuolization of the endothelium, and tearing and disappearance of portions of the endothelium. These changes are being investigated further and will be described in detail in a later communication.

To these remarks concerning the background of thrombophlebitis in varicose veins may be added a mention of two incidents which may produce a thrombosis in any vessel but which are very common as precipitating causes of thrombophlebitis in varicose veins. The most common one is trauma. The injury does not have to be a severe one, indeed, it is frequently an accidental kick of a child, or a mere bumping into an article of furniture. The second incident is the submission of the patient to the enforced bed rest, dehydration, etc., occasioned by childbirth, operation, or acute febrile disease.

CLINICAL COURSE²

The thrombophlebitis may start spontaneously or be precipitated by one of the incidents mentioned. It may be acute or chronic. The acute varieties give rise to greatly inflamed, tender, hard masses, somewhat wider than the underlying inflamed and thrombotic varices. The phlebitic process may stay localized to the original segment of vein and may subside in from 10 to 30 days or.

¹Varicose veins may give rise to a diminished arteriolar flow in two ways. The reflux down the saphenous increases the pressure within it. This pressure has been measured by several observers and has been found, under severe strain, to approach arterial pressure. The pressure is not only imparted to the varices, but, continuing through the venules it exerts a back pressure on the capillaries, which may equal the arteriolar pressure.

The second mechanism for the diminished arteriolar flow is to be found in the sympathetic nerve irritation and consequent arteriospasm which tense varices may engender (3).

²Nowhere in this paper is the expression "thrombophlebitis" used for the postinjection reaction in veins.

THROMBOPHLEBITIS OF VARICOSE VEINS

EDWARD A. EDWARDS, M.D. Boston, Massachusetts

THROMBOPHLEBITIS is a common condition occurring at some time in the course of about one half of all patients with varicose veins. It is a troublesome, usually painful, rarely a fatal condition. This paper will attempt to show that in spite of the customary cautious attitude which exists among most physicians, active treatment of the underlying cause, namely the varices, gives quick relief and is not dangerous.

Warnings against active treatment of the varices and the phlebitis are directed mainly against the use of sclerosing injections or operation during the presence of an active phlebitis (5, 16, 4, 27, 35, 25, 12). Several of the writers go so far as to prohibit injections until 6 months, 12 months, or even 2 years have elapsed after the acute attack.

ETIOLOGY

One gathers from the quoted writings that the avoidance of active treatment is based upon the presence of bacteria in the phlebitic veins. The proposition, however, that bacteria are present within the thrombus or the inflamed vein, while tacitly accepted, has not yet been proved.

At the outset the author should like to state that clinically the acute inflammation of phlebitis resembles that of infectious processes and it may be that future work will demonstrate microorganisms responsible for this process. At the present time, however, all the available facts point to the absence of pathogenic bacteria. This thesis has been more fully developed elsewhere (8). Briefly, the evidence against the presence of bacteria are:

1. The inability to find them by stain or culture.

2. The fact that lung infarcts which follow embolism from this source do not go on to abscess formation.

3. The usual absence of acute inflammatory exudate in the wall of the involved vein or in the regional lymph nodes.

4. The non-involvement of surrounding tissue except in the unusual form of ulcerating phlebitis of the foot described below.

5. The fact that operative procedures on the vein, including even curettage, do not result in sepsis.

6. The presence of thrombogenic factors, other than infection, in varicose veins which could by themselves produce a primary thrombosis and to which the phlebitis could be secondary.

This latter point has not been sufficiently developed, but several factors have been established. They may be grouped into three classes: slowing of the blood stream, physical and chemical changes of the blood, changes in the vessel lining.

Slowing of the blood stream. This has been shown by the work of Virchow and latterly by Aschoff to be the most important single factor in producing a thrombosis. It can hardly be doubted that the flow is indeed sluggish in the large sacculi which constitute varicose veins. This has been demonstrated to the author's satisfaction by the visualization of the venous blood in performing vasography. McPheeters, using this method, has published excellent demonstrations of this same fact (22). In his plates may be seen small masses of injected lipiodol floating around within the varices with almost no progressive movement.

The tortuous course of the varices and the presence of outpocketings furthermore produce whorls in the circulating blood. Whorls have been shown to facilitate the deposition of platelets which start the thrombosis (1).

Physical and chemical changes of the blood. The cyanosis of a varicose extremity is a good indication of the diminished oxygenation and deTakats and others (6) indeed found the carbon dioxide content of the blood in varices to be increased above that of the arm veins. This anoxemia is produced first by the stagnation of the blood and secondly by the fact that in severe varices the blood runs downward in the saphenous from the femoral vein. It is thus, so to speak, supernaturated blood. An increase in carbon dioxide content is said to enable blood to clot more easily, perhaps by increasing its calcium content.

The viscosity and protein content of the contained blood is also increased. An increased viscosity allows easier agglutination of cellular elements. The increase in protein is not wholly due to mere blood concentration as its rise is proportionately higher than the concentration and

Fig 5 The valve in "sclerosing phlebitis" Compare this with the normal valve of the same magnification in Figure 6 The normal cusp is thin and long, only a quarter of it being visible in this view It projects proximally, and as it does so it forms the internal boundary of the sinus In this situation, this thin flexible valve is ready and efficient in preventing back-flow The phlebitic valve sinus has become filled with fibroblastic tissue. This same material has greatly thickened the proximal half of the cusp Most important of all, the inflammatory tissue on the distal side of the cusp has pulled it down and anchored it to the vein wall in this reversed position The valve is therefore stenotic and regurgitant to such an extent that the vein is practically valveless The vein wall itself shows a fibrosis There is no evidence of any thrombosis No bacteria were found in several sections Verhoeff's elastic tissue and Van Gieson's stains $\times 25$

Fig 6 The normal venous valve (saphenous vein) Only part of one cusp is shown. Verhoeff's elastic tissue and Van Gieson's stains $\times 25$

undergoes a softening. Thus, anywhere from the third to the seventh week, when the inflam-

being considerably narrower than the saphenous, again offer an effective mechanical obstruction With the patient in bed, the blood no longer flows distally in the saphenous but rather in the normal direction toward the femoral vein. Under these circumstances, the thrombus may break off and be carried proximally into the femoral and so to the heart Furthermore, with bed rest a propagation of the thrombus is accelerated, especially, as has been noted, into the deep veins of the leg or thigh Most pulmonary emboli from varicose veins arise from these propagated clots, rather than from the thrombus in the saphenous or its tributaries

As already noted, pulmonary infarcts resulting from these emboli do not give rise to pulmonary abscesses Locally, the thrombophlebitis seems just as bland (Figs. 1, 2). Suppuration has been said to occur but rarely. In actual practice, I have not seen a single instance. Occasionally, the thrombus is not entirely organized but rather

Fig 7 Growth of hair along a phlebitic vein The patient, A J, was a 46-year old woman, referred by Dr Florence Clothier, of Boston Fourteen years previously, after a cesarean operation, she developed a left iliac phlebitis Large varicose veins followed, which were treated elsewhere by ligation in 1934. Due to large incompetent perforators, the hugely dilated varices persisted. In the summer of 1936 a very acute phlebitis was set off in them by a bruise This was followed in 2 months by the growth of hair The phlebitis was finally relieved by a section of the perforators performed during the active process

Fig 3 Ulcerating phlebitis. Below the lateral malleolus is a shallow ulcer while on the dorsum of the foot are several pigmented areas overlying small phlebitic veins. These lesions precede the ulceration.

This patient (H M) was a 43 year old man who in 1910 after a pneumonia suffered a phlebitis of both iliac veins. He then developed varicose veins which were elsewhere treated by saphenous ligation in 1935. The legs were improved but he continued to have attacks of ulcerating phlebitis of the feet each winter. The patient did not have diabetes or syphilis. A culture of the ulcer showed anaerobic staphylococci. He was treated with a vaccine of the organisms and a variety of dressings. Improvement was slow but steady and healing finally took place.

as frequently happens, the inflammation does not wholly disappear but lingers on, so that the process becomes truly chronic lasting from several months to a few years. On the other hand, the chronic process may start as such and in these instances one may find a true phlebitis with only a parietal thrombus or even no thrombus at all. Both the acute and chronic processes are prone to recur, and acute flare ups in the course of chronic phlebitis are common.

While the thrombophlebitis may stay localized, it usually progresses and it is not at all uncommon to find an additional 10 or 12 inches of vein involved in 24 hours. The easiest path of the process seems to be in the system of surface veins. Thus the phlebitis commonly extends upward to involve the entire length of the saphenous, and transversely, to involve its tributaries. Further extension involves the femoral vein by way of the saphenofemoral junction, or the deep veins of the leg or thigh by way of the perforating veins ("perforators"). Ordinarily the thrombus ends sharply at the junction, seemingly because there is such an active flow of blood in the femoral. If the patient is bed ridden, however, as after operation or childbirth, there is a good chance for direct extension to the femoral and I have seen several such cases of femoral thromboses.

Fig 4 Ulcerating phlebitis. section of the pre ulcerative lesion. A vein showing thrombophlebitis occupies most of the section. There is a minimum of reaction in the vein wall and in the surrounding tissue. A few clumps of chronic inflammatory cells are present including macrophages laden with blood pigment. The skin over the vein shows loss of its papillae and an increased desquamation. No bacteria were found by stain or culture. Verhoeff's elastic tissue and Van Gieson's stains. X40.

The patient (J D Boston City Hospital No 64,63) was a 47 year old man who had suffered from spontaneous varicose veins and ulcers complicated by severe diabetes and arthritis. The ulcers were successfully healed by saphenous ligation in 1933. Later the veins of the right leg recurred until a religation was performed in 1936 to section tributaries at the fossa which had been overlooked at the first operation. This disposed of the varices but in the spring of 1937, painful pigmented areas appeared on the lateral aspect of both feet appearing like those seen in Figure 3. Beneath them could be felt the thin hard cords of a phlebitis. One small ulcer appeared on the right foot resembling that seen in Figure 3. The section shown is that of a pre ulcerous area on the left. In this patient healing was effected by means of hot soaks and zinc peroxide paste.

The extension through the perforators is much more common. If the patient is active the deeper parts of the perforators may show only a parietal thrombosis or the complete process may progress into the perforators. Further extension into the deep veins of the leg or thigh is facilitated by the patient being bed ridden but is possible even if the patient is up and about.

Pulmonary embolism from a varicose thrombophlebitis does occasionally occur and may have a fatal outcome. It happens rarely, and perhaps not at all if the patient remains ambulatory. This may be explained by one of two facts. The first is that in all severe varices there is anatomical or at least functional valve loss and a consequent downward reflux of blood in the saphenous. If the patient is erect, the thrombus cannot escape by way of the saphenofemoral junction but is rather jammed downward in the leg. Here it can escape only by way of the perforators (9), which

Fig 5 The valve in "sclerosing phlebitis" Compare this with the normal valve of the same magnification in Figure 6 The normal cusp is thin and long, only a quarter of it being visible in this view It projects proximally, and as it does so it forms the internal boundary of the sinus In this situation, this thin flexible valve is ready and efficient in preventing back-flow The phlebotic valve sinus has become filled with fibroblastic tissue This same material has greatly thickened the proximal half of the cusp Most important of all, the inflammatory tissue on the distal side of the cusp has pulled it down and anchored it to the vein wall in this reversed position The valve is therefore stenotic and regurgitant to such an extent that the vein is practically valveless The vein wall itself shows a fibrosis There is no evidence of any thrombosis No bacteria were found in several sections Verhoeff's elastic tissue and Van Gieson's stains $\times 25$

as frequently happens, the inflammation does not wholly disappear but lingers on, so that the process becomes truly chronic lasting from several months to a few years. On the other hand the chronic process may start as such and in these instances one may find a true phlebitis with only a parietal thrombus or even no thrombus at all. Both the acute and chronic processes are prone to recur, and acute flare ups in the course of chronic phlebitis are common.

While the thrombophlebitis may stay localized it usually progresses and it is not at all uncommon to find an additional 10 or 12 inches of vein involved in 74 hours. The easiest path of the process seems to be in the system of surface veins. Thus the phlebitis commonly extends upward to involve the entire length of the saphenous and transversely, to involve its tributaries. Further extension involves the femoral vein by way of the saphenofemoral junction, or the deep veins of the leg or thigh by way of the perforating veins (perforators). Ordinarily the thrombus ends sharply at the junction seemingly because there is such an active flow of blood in the femoral. If the patient is bed ridden however as after operation or childbirth there is a good chance for direct extension to the femoral and I have seen several such cases of femoral thromboses.

Fig 4 Ulcerating phlebitis section of the pre-ulcerative lesion. A vein showing thrombophlebitis occupies most of the section. There is a minimum of reaction in the vein wall and in the surrounding tissue. A few clump of chronic inflammatory cells are present, including macrophages laden with blood pigment. The skin over the vein shows loss of its papillae and an increased desquamation. No bacteria were found by stain or culture. Verhoeff's elastic tissue and Van Gieson's stains. X40.

The patient (J D Boston City Hospital No. 64 63) was a 47 year old man who had suffered from post-traumatic varicose veins and ulcers, complicated by severe diabetes and arthritis. The ulcers were successfully healed by saphenous ligation in 1933. Later the veins of the right leg recurred, until a religation was performed in 1936 to section tributaries at the fossa which had been overlooked at the first operation. This disposed of the varices but in the spring of 1937 painful pigmented areas appeared on the lateral aspect of both feet appearing like those seen in Figure 3. Beneath them could be felt the thin hard cord of a phlebitis. One small ulcer appeared on the right foot resembling that seen in Figure 3. The section shown is that of a pre-ulcerous area on the left. In this patient healing was effected by means of hot soaks and zinc peroxide paste.

The extension through the perforators is much more common. If the patient is active, the deeper parts of the perforators may show only a parietal thrombus or the complete process may progress into the perforators. Further extension into the deep veins of the leg or thigh is facilitated by the patient being bed ridden but is possible even if the patient is up and about.

Pulmonary embolism from a varicose thrombophlebitis does occasionally occur and may have a fatal outcome. It happens rarely, and perhaps not at all if the patient remains ambulatory. This may be explained by one of two facts. The first is that in all severe varices there is anatomical or at least functional valve loss and a consequent downward reflux of blood in the saphenous. If the patient is erect the thrombus cannot escape by way of the saphenofemoral junction but is rather jammed downward in the leg. Here it can escape only by way of the perforators (9) which

The patient was a 36 year old, unmarried woman, referred by Dr George Gorham of Roslindale. She had suffered for 20 years with a universal, progressive arthritis, so that all her joints were stiffened and presented only a few degrees of motion. She spent most of her time half reclining in an easy chair. Aside from the chronic arthritis there had been no episodes suggesting phlebitis and no rheumatic fever.

In February, 1933 an ulcer had appeared spontaneously on the medial aspect of the left leg, just above the ankle, and in a few weeks this was followed by a second one a few inches lower. The ulcers were never entirely healed, although 3 weeks' bed rest in 1935 had resulted in their getting much smaller. On resuming her usual restricted activity, the ulcers enlarged to their previous size. The patient was anxious to have the ulcers treated because they gave her considerable pain.

Examination disclosed a thin limb with almost complete ankylosis of hip, knee, ankle, and toes. On the medial aspect of the lower third of the limb were 2 ulcers, one 3 centimeters the other 4 centimeters in diameter. Both were bluish with dull granulations in their bases and with no undermining of their edges. There was moderate brown-black pigmentation above them. The saphenous was made out as a hard cord in which a slight percussion impulse could be transmitted. The Trendelenburg test was not tried. Above the upper ulcer was a soft area suggesting an underlying dilated perforator. Bacteriological culture of the ulcer was done by Dr J B Hazard who reported: "Aerobic culture—*Bacillus proteus*, *Bacillus coli*. Anaerobic (chopped meat)—In addition to gram-negative bacilli, contains a gram-positive coccus occurring in pairs and short chains, probably streptococcus." There was no sugar in the urine and the blood Hinton test was negative.

After 4 days of hot applications of chlorinated soda solution the streptococci were absent and only staphylococci were present. At this time, September, 1936, a high ligation of the saphenous was performed. The vein was small and adherent to the surrounding tissue. It contained a shrunken, thickened valve (Fig 5). Six days after the ligation the ulcers were healed so that the section of the perforators, which had been thought necessary, was not performed. The ulcers have remained healed to this date.

TREATMENT

Varicose phlebitis has generally been treated in a conservative fashion. This has for the most part consisted of rest in bed and the application of ice packs. Such treatment is not satisfactory. The application of ice has a devitalizing effect on the tissues and promotes thrombosis. The enforced rest facilitates the propagation of the thrombosis and increases the chances for pulmonary embolism. It may take weeks or months of such rest before the process quiets down. Foot drop and shortening of the tendo achillis may occur during this prolonged bed rest. Other trophic disorders, such as the growth of hair over the affected vein, are occasionally seen (Fig 7). This resembles the linear growth of hair observed by Louste and Levy-Franckel and by McPheeters (21).

Finally, the long period of disability necessary for this treatment is of no lasting benefit to the

patient. The varices recanalize and sooner or later the phlebitis recurs.

Fischer, in 1910, suggested that phlebitis of varicose veins be treated by the application of a tight bandage and walking. In 1929, Deutsch reported 600 cases, and in 1930 Jaeger reported 100 cases, treated in this fashion with no instances of pulmonary embolism. This was a distinct advance in the conservative treatment since it allowed the patient to stay at his work, diminished the extension of the phlebitis and the chances for embolism.

Starting with Tavel in 1907, who used ligation followed by phenol injections (33), there have been many workers who have disregarded the numerous warnings against the injection of varicose veins in the presence of phlebitis (26, 20, 3, 2). All have reported excellent results by the injection treatment, in the delimitation of the phlebitic process and the subsidence of the inflammation. The injections have generally been used along with the elastic bandage and walking. Such a regimen is a very good one in so far as the active process is concerned, but the closure of the veins produced by the injection is hardly of more lasting effect than that produced by the phlebitis, and recanalization is the rule.

Surgical treatment has also been essayed with good results. The type of operation has varied between curettage of the thrombus, excision of the thrombotic veins, and ligation of the saphenous. Incision of the vein and curettage of the clot was reported by Eisenklam in 1929. He noted no untoward results. The wounds did not become septic, and the inflammation subsided as soon as the clot was removed. This observation makes more plausible the probability that no infection is present and that the inflammation is secondary to a primary thrombosis. This was again advised as one method of treatment by McPheeters in 1931. Excision of the involved segment of vein was reported by Moullin in 1904 as a simple and safe means of cutting short the course of the phlebitis. Homans, in 1928, again reported this as the method of choice.

Tavel in 1904 was apparently the first to advise ligation of the saphenous for its effect on healing the phlebitic process (34). It appears that later he definitely added postoperative injection of 5 per cent phenol to the treatment (33). In recent years deTakats (5) and McPheeters (20) have both recommended ligation when the saphenous is greatly widened. Others have recommended ligation primarily to prevent embolism (32, 31). From the previous discussion it would seem that the prevention of embolism is accomplished mostly

mation has quite well sub sided one or more areas, each from 2 to 4 inches in length become red fluctuant, but not particularly tender. In a day or two, these areas point and open spontaneously, discharging a sterile grumous material. Almost immediately the local inflammation disappears and the tiny sinus is healed within a week.

When a patient is seen with a firm thrombosis of the entire saphenous up to the fossa ovalis, the question may arise as to whether this closure of the vein will not give a spontaneous cure. The answer is, unfortunately, in the negative. I have never seen such a closure remain permanent. Recanalization seems rather to take place faster and more completely than elsewhere in the body, so that at the end of 2 or 3 months a good sized lumen is apparent. The varices then always recur after the resolution of the thrombotic veins.

There is significance in the fate of the venous valves during the course of the phlebitis. With Jesse Edwards I have previously shown that the organization and recanalization of a thrombus results in a destruction of the venous valve (10). We also found that an incomplete thrombosis such as occurs in the upper end of the saphenous or in the perforators, either destroys the valve or produces a stenosis and regurgitation.

The valvular status of the ordinary varicose extremity has been remarked on for about two centuries. The most significant finding in any severely varicose extremity is a relative or absolute insufficiency along the great saphenous trunk and some of its tributaries. Occasionally one or more perforators may also be valveless. There are usually present, however, some normally valved tributaries and normally valved perforators. The additional destruction occasioned by the phlebitis affects whatever normal valves may still be present and throws the veins into the class of full fledged varices. Especially serious is the destruction of the valves of the perforators as this will allow a reflux from the deep to the surface veins. This interferes with the normal return of blood flow, by the pumping action of the muscles and such a limb presents an even more serious impairment of the venous circulation than does the usual varicose limb.

ULCERATING PHLEBITIS

By this expression I refer to a chronic thrombophlebitis of the surface veins occurring oftentimes on the dorsolateral aspect of the foot. This is a very unusual location for varicose veins and indeed these veins are not particularly widened. The process is seen most frequently in patients who have had a deep phlebitis preliminary to

their varices. An itching pain is complained of early, and examination shows an indurated inch or two of vein, with the skin pigmented and adherent to it. In a few weeks the process may resolve or more often the skin sloughs immediately over the vein to give rise to a shallow, painful, and intractable ulcer (Figs 3-4). Section and culture of the vein and skin in the pre ulcerous stage in 2 instances has disclosed no bacteria. Once formed the ulcer does, of course, contain bacteria. Because of the anoxemia in the diseased limb, these are apt to be anaerobic streptococci and staphylococci. The ulcer does not respond to the treatment of the varices above but can be healed by local excision, by the use of local antiseptics (especially zinc peroxide, 2%) by the use of vaccines or non specific protein therapy or by local hyperemia, as by the iontophoresis of metholyl (30).

ASCENDING SCLEROSING PHLEBITIS

By this expression I refer to a form which starts in the normal superficial veins of the lower limb. Its onset may not be traceable to any acute episode as an acute febrile disease or postoperative state. The reason for including it in a discussion of varicose phlebitis is that it gives rise to the same valvular insufficiency and then continues in the now valveless saphenous system. Though the resultant veins are not dilated yet the hydraulics of blood flow are disturbed in the same fashion as in any varicose veins and trophic disorders including ulcer are even commoner.

The disorder usually starts at the ankle as a chronic phlebitis of the superficial veins with or without thrombosis. Quite commonly there is so little disturbance that the patient may be unaware of the process until an ulcer has occurred. Or the patient may present himself for a slightly tender leg with some edema of the dorsum of the foot and ankle, and symptoms of sympathetic nerve irritation, namely coldness and local sweating (8). The process proceeds in several months to ascend in the saphenous and also to involve the perforators. When the active inflammation is over the veins can be palpated as hard cords which on pressure depress the overlying skin into a linear furrow. The ankle is pigmented and an ulcer may be present with all the characteristics of a varicose ulcer. Truly varicose veins cannot be found the vessels seemingly being too tough to dilate.

The course of this form of phlebitis is well illustrated in the case report which follows and also in the figure of a venous valve from the patient (Fig 5).

recanalize as surely as do those involved at a lower level. Obviously, one should handle such a vein gently, but I have never seen recognizable pulmonary embolism following ligation of such a vein, and Dr. Homans has stated that this is also his experience.

The first time the patient is seen, the vein may be so completely closed by the thrombosis that it is impossible to perform the Trendelenburg test or otherwise to determine whether the vein has previously been sufficiently varicose to be valveless. However, since it is the rule that the vein will recanalize and will then be valveless, the operation is indicated just as surely as on those veins which were known to be previously varicose. This brings up the point of "phlebitis in hitherto normal veins" (Homans). Some of these are small varices which have not been recognized as such. Others are instances of idiopathic phlebitis and still others are cases of migrating phlebitis. In the first two, ligation is indicated. Migrating phlebitis, however, is so frequently an expression of Buerger's disease that ligation or injection should not be used. In the light of our present meager knowledge of this condition, these should rather be handled conservatively.

A second operation which must occasionally be performed in these patients is the section of incompetent perforators. The valves of the perforators are apt to be destroyed or become stenotic and regurgitant by involvement in a phlebitis of the deep veins or, as noted, in a phlebitis of the superficial veins. Incompetence of the perforators with a doubly positive Trendelenburg test is therefore seen a little oftener in these patients than in those who have not had phlebitis. My method of handling them is first to attempt healing of the phlebitis and the varices by ligation and injection. If the varices cannot be kept closed by this method, the incompetent perforators must then be sectioned. This operation can be done at the very start, but in most patients healing will take place without it. The technique of the section is that recently described by Faxon and by Linton (Fig. 8).

The subsequent injection of the varices deserves some special mention. While I cannot readily agree that injection stirs up *infection*, there is no question but that it may stir up the *inflammation*. It is a frequent occurrence to see spontaneous attacks of phlebitis in both legs of the same patient so that these veins may be termed thrombophilic. If one injects the veins of every phlebotic patient with the same dose of sclerosing fluid used in uncomplicated varicose veins there may be an extension of the phlebitis

and an increase in the degree of the inflammation. It is best to try out the individual patient's reaction by injecting about 0.5 cubic centimeters of 5 per cent sodium morrhuate the first time, and then increasing this slowly to a total dose of 2 to 5 cubic centimeters at a visit.

If the inflammation is marked to begin with, it is better simply to ligate and to postpone the injections for a week or a month. In the meantime, the reaction will be lessened by hot compresses of magnesium sulphate solution and by exercise. If the patient is an active person with no unusual sensitivity to pain, it is better for him to have a firm elastic bandage or stocking applied after the ligation, and to remain ambulatory. Occasionally, in an older person, or sensitive individual, the patient may stay in bed but should carry out regular exercises. The leg is elevated on one or two pillows. Every 2 hours the patient raises the leg in the air and "bicycle rides" 6 times. If there is much edema, it is well to alternate this raised position with 2 minutes of dependency, as in Buerger's exercises.

I have no figures on the number of patients treated by ligation and injection who had a previous history of deep or superficial phlebitis but they constitute a very large group. In none of them did any serious complications arise and only occasionally did the injections seem to reactivate a superficial phlebitis, which soon subsided. I have never seen a reactivation of a deep phlebitis.

Ligation followed by injection was performed on 63 patients during *acute phlebitis*. Thirty of these were private patients. The 33 others were personally observed and followed at the circulatory clinic of the Boston City Hospital. The postoperative course of the phlebotic patients resembled that of patients with uncomplicated varicose veins. With the exception of 5 patients who remained more than 1 week, the average hospital stay was $2\frac{3}{4}$ days. During this hospital stay most of the inflammatory reaction subsided, and the progress of the phlebitis was stopped. There was no unusual incidence of wound sepsis and not a single instance of postoperative pulmonary embolism. The average time out of work was only slightly longer than that in the uncomplicated cases, 1 to 3 weeks as compared with 5 to 10 days. In an occasional patient the inflammation subsided slowly or was stirred up by the subsequent injections, but this rarely confined the patient to bed.

Not only is the attack of phlebitis arrested but at the same time the varices are treated. The patients have been followed from a few months

Fig 8 The technique of section of incompetent perforators as suggested by Linton (Perforating veins whose valves are incompetent) Since most of the perforators run into the posterior tibial veins the incision is usually placed medially. As the deep fascia is turned forward the perforators are seen in little clumps often in association with a small artery. Those previously involved in phlebitis are apt to be surrounded by scar tissue. All visible perforators whether apparently normal or abnormal are doubly ligated and sectioned. Insert shows a perforator entering a varicose vein in the superficial fascia.

through the ligation allowing the phlebitis to heal and diminishing its propagation to the deep veins.

Comparing the various forms of treatment suggested it would seem that it would indeed be best to attack the varices proper, provided this attack would not increase the phlebotic process nor the chance for embolism. In practice treating phlebotic varices as though they were uncomplicated varicose veins gives good results. Reference is made to the ligation of the saphenous at the saphenofemoral junction, later followed (if

some of the varices are patent) by injection of the varices. The patient does not have to wait until the acute process is over, for the treatment relieves the phlebitis, probably by removing the pressure of the overlying blood. Ligation is therefore done at once. I reported on this treatment in 1934 and subsequent experience has convinced me it is the method of choice (9).

The operation has been performed on several veins which have shown a thrombosis right up to the saphenofemoral junction, since these veins

to 5 years, and to date no patient has shown a recurrence of either the varices or the phlebitis

SUMMARY

Thrombophlebitis is a common complication of varicose veins. Left untreated or treated by the older method of rest in bed, it progresses in the surface veins and by way of the perforators to the deep veins. It is especially from this deep extension that pulmonary embolism may occur. The disability of the disease extends over weeks or months with recurrence of the varices and the phlebitis the rule.

Warnings against a direct attack on the varices during the period of phlebitis has for the most part been based on the assumption that phlebitis is due to infection. Actually, this infection, though possibly present, has never been demonstrated. There is more evidence that a primary thrombosis occurs due to factors inherent in the varicose widening, and that the inflammation of the vein is secondary to the presence of the thrombus.

The most effective treatment is based on the attitude that the phlebitis is but a complication, and the treatment is immediately directed against the varices. It is therefore very similar to the treatment of uncomplicated varicose veins. It consists of a ligation of the saphenous at the sapherofemoral junction, this being followed by regular exercise and if necessary by the application of heat. Injections of sclerosing solution can be used if some of the varices are still open but should be given in small doses as otherwise the inflammation may temporarily be augmented. Sixty-three cases have been treated in this way with entirely good results. The special advantages of this treatment are the brief period of disability (1 to 3 weeks), the lessening of the chance for pulmonary embolism, the prevention of further damage of the valves of the perforating or deep veins, the prevention of recurrence of the phlebitis and the simultaneous and immediate treatment of the varices.

Two special forms of varicose phlebitis are described. The first ulcerating phlebitis refers to a thrombophlebitis of the surface veins at the ankle and on the foot. Almost invariably the skin over these veins becomes adherent to the vein and sloughs forming ulcers which are resistant to treatment. For their successful cure they require local excision or amputating treatment.

The second form 'chronic sclerosing phlebitis' is a spontaneous chronic inflammation of the surface veins of the leg which goes on for months or years and ultimately cripples or destroys the

valves of the saphenous system. For this reason, these patients have the same trophic disorders that ordinary varicosities give and must be treated in the same way.

CONCERNING THE HEREDITARY NATURE OF CANCER

DESPITE the unceasing efforts of scientist, surgeon, and radiotherapist, the problem of cancer baffles all attempts at solution. Many cures are achieved, sometimes when least expected, yet the origin of cancer, and its nature, remain unsolved. That its increasing spread will threaten human existence has been predicted. Faced by cancer in his immediate family, man's innate fear is betrayed by his perennial question "Doctor, is it catching?" Moreover, a folklore superstition as to its familial character hauntingly disturbs his peace. To prevent awakening in him an unnecessary dread of the future, his doctor usually assumes an attitude of reassurance, and is wont to minimize the hereditary nature of cancer.

Convincing evidence against this attitude is provided by Maude Slye's brilliant contributions from the experimental laboratory. Additional corroborative evidence is available from the following clinical experiences:

A family. A young girl, 18 years of age, still living has had her right breast removed for cancer. Her mother died at 47 of bilateral carcinoma of the breast, one maternal aunt, still living, has had both breasts removed for cancer; a second maternal aunt, still living, has had one breast removed for cancer. Her maternal grandfather died of cancer of the colon. One maternal great aunt died of bilateral cancer of the breast. A second maternal great aunt died of cancer of the uterus. A maternal great-great aunt died, aged 40, following bilateral mastectomy, presumably for carcinoma.

B family. Three brothers died of carcinoma of the prostate. The mother had died of a pelvic malignancy, presumably of the reproductive organs.

C family. A young girl died at 30 of cancer of the breast. Her paternal grandmother had died at 26 of cancer of the breast. A maternal aunt had died at 49 of cancer of the kidney; a maternal uncle had died at 45 of cancer of the stomach; her maternal grandmother had died at 55 of cancer of the stomach.

D family. A patient under treatment for cancer of the tongue gave the following family history: A sister died of cancer of the tongue. Her father died of cancer of the jaw. A paternal uncle died of cancer of the hip and a son of this uncle died of cancer of the jaw.

E family. A patient under treatment for inoperable cancer of the cheek and jaw gave the following incredible history: His paternal grandfather died of cancer, site unknown. His paternal grandmother also died of cancer, site unknown. His father died of cancer of the face at 90. Three paternal uncles have cancer of the face or jaw and three paternal aunts have cancer of the breast. The son of one of his paternal uncles has cancer of the face.

These striking examples from a small clinic strongly substantiate the conviction in the minds of many writers that there exists a hereditary factor in the development of cancer.

McKenney's mournful record of two families of 46 members, 37.7 percent of whom have or have had polyposis of the colon, followed in these up to the present time by death from cancer in 44 percent, provides additional arresting evidence. As concrete proposals in the campaign to eradicate or to limit cancer, the following suggestions are made:

A NEW McDONALD'S SOLUTION

FRANCE McDONALD M.D. C.M. F.A.C.S. Philadelphia, Pennsylvania

TWENTY TWO years ago, I published the results of experimentation upon a new solution for disinfection of the hands and abdominal skin before operation. This came to be known as McDonald's solution.¹

Fourteen years ago I published a review of the results with that solution along with some other work on disinfectants, drawing attention to the fact that at that time para hydroxy diphenyl was considered to have the highest germicidal value.²

There was a hope that a pure substance might be found to take the place of the heavy tarry extract which with acetone and alcohol was the basis of the original solution.

Para hydroxy diphenyl, while perfectly satisfactory for the alcohol acetone solution, is not soluble in water. A better substance has been suggested to me by Mr Leland Doan of the Dow Chemical Company and this has now been used by me and a number of surgeons for 7 years. It is sodium ortho-phenyl phenate with this structural formula and is more potent than the old solution.

The new solution

Sodium ortho phenyl phenate
Sodium oleate
Acetone
Alcohol 92%

1 part
2
2
600

This solution has the advantage of dissolving the fat in the skin and allowing penetration of the sweat glands etc. It is not neutralized by organic matter or soap. Sodium ortho-phenyl phenate has a phenol coefficient of 18 against the typhoid bacillus.

The following directions in the use of my method are given as it is very commonly misunderstood.

(McDonald Ellise Surg. Gynec. & Obst. 1913 31 83)
(McDonald Ellise Am. J. Obst. & Gynec. 1923 Oct. vol. 41)

From the Bio-Chemical Research Foundation of the Franklin Institute

Directions for disinfection of the hands (McDonald method) As washing the hands with soap and water has little or no effect upon the bacteria of the skin even if kept up for 15 minutes it is advisable that some germicide should be added to the wash water. This germicide should be one which is not neutralized by soap or organic matter as contained in the skin, so the new solution one part to 30 of water is used in the basin of warm water.

The area under the nails is the most difficult place to disinfect and, therefore particular attention should be given to the introduction of the germicidal solution under the nails. Nail brushes should be used for the nails only and wash cloths for the hands and arms.

1. Wash the hands in soap and water, containing McDonald's solution 1:30 in a basin for 2 minutes. Scrub the nails with a nail brush and the hands and arms with a cloth. This solution may be used repeatedly. This thorough scrubbing is done only at the first operation and after this the time may be reduced to 2 minutes.

2. Keep wooden orange sticks and nail files in McDonald's solution and do the toilette of the nails, making an effort to introduce the solution under the nails by means of the wet nail file and orange stick.

3. Hands should then be washed in McDonald's solution for 3 minutes scrubbing the nails with the nail brush and using a cloth for the hands and arms. The solution should be at least 3 inches deep in the basin. The hands are then dried and prepared for gloves.

Preparation of patients Shaving the night before operation should be done with water containing McDonald's solution 1 part to 30 parts of wash water. In this way the shaving water will be a germicidal solution and will disinfect, and as the skin is again disinfected the next day, fractional sterilization will be practiced. At operation the dry towel is removed and the area of operation rubbed lightly with a small towel or piece of gauze saturated with McDonald's solution for 3 minutes. The skin is lightly dried and the alcohol and acetone evaporate very quickly leaving the site of operation ready for the incision.

operation of such an instrument. The confusion of thought that exists regarding surgical diathermy probably results from failure to recognize that surgical diathermy differs from electrocauterization in mode of action and in effect. The wire loop, at the end of the electrocautery handle, is made of an electrically resistant metal which becomes red, or even white, hot when a current is passed through it. The electrocautery destroys tissues by conduction of heat from this hot loop to the tissue. Surgical diathermy, on the other hand, utilizes an electric current of high frequency; this current will not produce an electric shock if allowed to pass through the tissues of the body, rather it produces destruction of the tissues because they offer resistance to the flow of the current. When the current is concentrated in the tissues at the tip of a needle, varying degrees of endogenous heating, or even actual disintegration of tissue will occur when the tip is applied to it. Unlike the cautery, the needle at the end of a surgical diathermy handle is constructed of metal of low electrical resistance. The needle, therefore, remains comparatively cold, but the tissue near the needle or in contact with it offers resistance to the flow of the current from the needle. The tissue, therefore, is heated or desiccated. Surgical diathermy is so frequently regarded as a form of cauterization that an explanation of the differences in the mechanism involved seems essential. Not only are the cautery and surgical diathermy entirely different in construction and effect, but also the accuracy of control of the latter is much more delicate than that of the former.

Monoterminal application of surgical diathermy, in which the active needle is attached to a single terminal of the diathermy machine by an insulated wire, is spoken of as "fulguration" or "desiccation." Fulguration is accomplished by holding the needle a short distance

from the lesion which is then showered with sparks and carbonized. Desiccation is accomplished by placing the needle in contact with the lesion, or by inserting the needle within the lesion. With this slight exception the procedures are practically identical, and the terms "fulguration" and "electrodesiccation" are often used synonymously.

Biterminal application of surgical diathermy consists of attaching the needle to one terminal of the diathermy machine by an insulated wire. A large "indifferent" plate is placed in contact with the body of the patient at some site remote from the lesion. This is attached by means of a wire to a second terminal of the diathermy apparatus. Biterminal applications are used in electrocoagulation and in electrosurgical cutting.

High frequency oscillating current used in fulguration, electrodesiccation and electrocoagulation is a damped current, that is, the amplitude of successive vibrations varies by gradual change from a maximal to minimal degree, and from minimal to maximal degree. This sequence is continuous. Such a damped current is produced by the spark-gap type of diathermy machine. On the other hand, high frequency oscillating current used for cutting tissues, is undamped, that is, the amplitude of successive vibrations does not vary from the maximum. Such an undamped current is usually produced by means of the tube (or valve) type of diathermy machine. Whereas a damped high frequency current tends to coagulate tissues, an undamped current causes actual disintegration which results in solution of continuity of tissues; this latter type of current is called the "cutting" current. Fulguration or desiccation produces very superficial carbonization, or destructive dehydration of tissue. Electrocoagulation, on the other hand, is applicable to the destruction of large malignant growths. An entire growth may be

That the genetic factors in the development of human cancer be accorded greater importance

That the multiple occurrence of cancer in a family, or in two generations demands a frank discussion with other members of that family and with members of succeeding generations concerning the known hereditary aspects of cancer. Alarming prophecies are unnecessary and unwarranted, but such a discussion with those members vitally concerned would unquestionably evoke the greatest co operation from them in undergoing periodic health examinations in promptly seeking advice for painless and to them insignificant lumps, in avoiding or in eliminating sources of irritation, and even in restricting further reproduction

That the multiple occurrence of cancer in a family or in two succeeding generations is sufficient medical and legal evidence to warrant sterilization when desired, or abortions when necessary. The question arises also whether, ultimately for the good of the race compulsory sterilization might in certain instances, be desirable

That the marriage of two persons both members of cancerous families be preceded by explicit instructions concerning birth control, or by sterilization of the male in a manner revocable later if desired

That the familial characteristics of human cancer be the subject of intensive clinical study. The greater accuracy of diagnosis and the greater accessibility of proper care to all patients make such a study more trustworthy and more practicable now than formerly. To make the necessary facts available for study and integration it is suggested that the American College of Surgeons be made a repository for the complete records of all authenticated cases of familial cancer including microscopic slides, descriptions of cases,

family trees, and present progeny. Once so documented and recorded, the members of a given family may be subjected to more intensive studies concerning the anatomical, physiological and environmental factors inherent in this family. Such a study requires the assistance of a perpetually available organization like the American College of Surgeons to insure continuity from generation to generation. Indeed the Fellows of the College in their various communities could, quietly, without public discussion or neighborhood gossip place families on record for future study by successive generations of Fellows all to the ultimate benefit of medical science and therefore of humanity

EMILE HOLMAN

ELECTROSURGERY

ELECTROSURGERY may be considered under three divisions (1) time honored electrocauterization, (2) surgical ionization now seldom used, and (3) surgical diathermy which is most important. Electrocauterization needs little description as the principles underlying its use are well known to all surgeons. Surgical ionization plays a minor rôle in the treatment of superficial lesions and in the process of epilation. Destruction of tissue is brought about by concentration of caustic acid or alkaline ions in the tissue in contact with a needle through which a constant electric current is allowed to pass.

Modern surgical literature is replete with references to surgical diathermy. This form of electrosurgery merits careful consideration. The surgeon's chief concern is not with the construction of a complicated electrosurgical instrument rather, it is with the possibilities that such an instrument may offer in the treatment of surgical conditions. Nevertheless, it is well to understand certain principles of the

Electrosurgery undoubtedly has produced radical advances in transurethral surgery. Scott has found it of value in other forms of genito-urinary surgery, such as in removal of calculi or in resection of the lower pole of the kidney.

In the hands of such men as Kelly and Ward, electrosurgery has found extensive use-

fulness in gynecology. The coagulating current has been used most widely for the destruction of many minor cutaneous lesions as well as of extensive superficial malignant growths.

Certainly, electrosurgery should merit the continued interest of all surgeons.

FRANK H. KRUSEN

coagulated and removed *en masse*. There is a tendency for the blood vessels and lymphatics in the surrounding tissues to be sealed by thrombosis, thus minimizing the danger of hemorrhage, shock and dissemination of malignant cells.

A modification of the method of electrocoagulation is produced by the employment of two electrodes, such as two needles, or two prongs of a clamp. By the use of this technique coagulation of tissue will occur only in the region that lies between these electrodes.

Various designations have been applied to the apparatus used for electrosurgical cutting such as, 'radio knife', 'electrothermic knife,' 'Bovie knife,' 'endothermic knife,' and 'acu sector'. The last term coined by Howard Kelly, is derived from the two words 'acu' ('with a needle') and 'seco' ('I cut'). By use of this method the tissues are cut rapidly or slowly, the needle dividing the tissue "as a knife cuts butter". Histologically two zones of tissue may be observed. There is evidence of molecular disruption in the zone adjacent to the incision, in the zone immediately beneath this one there is evidence of elongation of the tissue cells and slight coagulation. Properly applied, the 'sector' (cutting needle) coagulates the wound so slightly that there is a minimum of interference with the process of healing, and there is usually marked diminution of oozing from capillaries.

Nelson Lowry said "There have been two distinct schools in electrosurgery, the cutting school and the cooking school". It is generally believed that the surgeon who utilizes both "cutting and cooking" (electrocoagulation) in each operation will obtain the best results.

Howard Kelly and his associate Grant Ward stated that the demand for electrosurgery had occurred because of the inherent imperfections in operative technique. The necessity for ligation of blood vessels, the possibility of dis-

semination of infectious agents or malignant cells, and the inability to obtain adequate hemostasis in inaccessible parts of the wound are for the most part obviated by the use of electrosurgical technique. Only those who are inexperienced in the use of high frequency current encounter much difficulty. Kelly and Ward stated that the delay in acceptance of electrosurgery by the medical profession probably was attributable in part to the fact that the apparatus was still in the stage of development and in part to lack of persistence in the attempt to develop a technique for its use.

Surgical diathermy has proved particularly efficacious in certain surgical procedures, and in time, as new techniques are developed, it will undoubtedly be more extensively used. Already it has acquired a definite place in the field of neurosurgery. Cushing was an enthusiastic advocate of electrosurgery, and Adson applies it routinely for hemostasis in various types of neurosurgery.

Kirschner of Germany, published reports of 250 cases in which electrosurgery was used. He advocated its use, particularly in amputation of the breast for carcinoma, and in operations on the thorax especially in resection of a rib or in thoracoplasty. Heymann observed that electrosurgery was effective in incision and enucleation of furuncles and carbuncles and in the eradication of extensive collections of purulent material. Hesse was of the opinion that electrosurgery is of special value in the treatment of malignant diseases of the nose and throat particularly small malignant growths of the larynx and of the maxillary sinuses.

A number of authors Mock, Tinker, Jackson and Heymann have enthusiastically advocated the use of surgical diathermy in operations on the thyroid gland, particularly in operations necessitated by the presence of malignancy or toxic exophthalmic goiter.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE recent book¹ by Dr Hollender and collaborators satisfies a need of otolaryngologists. It deals with every form of physical therapy that has been used in the treatment of diseases of the ear, nose, and throat.

From the earliest time physical therapy in some form has been employed by all physicians in this specialty. Not many years ago physical therapy included the use of little more than heat or cold, wet or dry applications, light or darkness. Now it involves among other things heat from many sources, light of many varieties, electricity produced by numerous machines, and radiations of various kinds. The field is extensive and complex. The technical phases of the subject are handled in a very satisfactory manner by Dr Hollender. The details are sufficiently described in terms that are easily understood.

As a guide to technique in physical therapy in otolaryngology Dr Hollender's book has real value.

ELLISON L. ROSS

THE intent of Friedman in his *Textbook of Diagnostic Roentgenology*² was to produce a helpful reference volume for the radiologist, in which the student and mature practitioner should find no difficulty in following the trend of the methods of roentgenologic diagnosis. The book admirably fulfills the author's expectations.

Part I deals with the fundamental principles of roentgenology, including a concise, but comprehensive, discussion of roentgen-ray physics. An interesting discussion of roentgenographic accessories and dark room procedure is included in this section.

Roentgenology of the osseous system comprises Part II, beginning with a discussion of the development of the various bones. Separate chapters are devoted to roentgenographic technique, fractures and luxations, diseases of bones and joints, skull, brain and spinal cord, diseases of the nasal accessory sinuses and mastoids, and dental roentgenography. Helpful classifications are presented at the beginning of these chapters.

The respiratory system, the cardiovascular system, the alimentary system and the genito-urinary system are considered in Parts III, IV, V, and VI, respectively. At the beginning of each chapter the author discusses the roentgenographic procedures employed in examining the particular organ or structure under consideration. This phase of the text

should be particularly helpful to the student and general practitioner.

The subject matter throughout the volume is well and concisely written, and includes not only roentgen findings but appropriate remarks concerning the etiology, clinical findings, and pathology of the particular lesion being discussed. The text is systematically arranged and easy to read.

The numerous illustrations are well chosen and well reproduced to show excellent detail. The reproductions of the roentgenograms have been transposed to the negative form. India ink drawings are frequently utilized to demonstrate conditions or procedures not obtainable by photography.

This excellent volume should interest not only the radiologist; the general practitioner will find it a useful guide in his work. The attention of teachers of radiology should be called to the excellence of this work as a radiological text.

JAMES T. CASE

THE literature for the period 1935 to early 1937 has been covered in abstract form in *The Pneumonokonioses (Silicosis) Literature and Laws. Book III*³. A few abstracts and bibliography titles omitted in previous editions have been added. Eight hundred and seventeen pages are devoted to abstracts of 701 articles covering the chemical, clinical, editorial, engineering (prevention and control), experimental, industrial relations, insurance, and legal phases of the dust disease problem. The abstracting is unbiased and in general well done, however, some of the briefs are rather too long to be serviceable. Many of the more important medical articles have been reprinted in their entirety. The material has been derived from numerous medical, engineering, and legal theses and journals, as well as from various committee, code and meeting reports; many of these sources are ordinarily inaccessible to the average reader. The extensive index has been divided into three divisions: author, medical, and subject. A simpler system would be more useful.

Part II of this volume devotes 130 pages to the legislative phases of the problem. Here the pertinent points of, and decisions under, the occupational disease acts and other statutes related thereto of the various states, provinces of Canada, and some foreign countries, are cited. The recently enacted Illinois and Indiana occupational disease acts are quoted very extensively.

Anyone interested in the pneumonokonioses will find this volume a most useful compendium and

1 Broadway Park
New York
President Lincoln May 11 1862

Dear Sir,

As a private citizen
I give permission to you to publish your own
a subject that is true to our plan
I have heard -

The Labor Union in England
- take notice of a few laborers
in the accompanying pamphlet
with explanation. It is our
purpose to do this later on.
- I wish to see from the beginning
as the labor union is
- true - it is also the foundation
of the labor union -
and the labor union -

sent me by the committee within a
few days - they asked if you
it down the very early edition
and was not told not to have
any more sent in - the paper
the same was not signed
any private committee for a day
- done - Yours truly
(Mott)

source book of the recent literature. It is hoped that the authors may continue this fine work of assembling in abstract form all the information relative to this timely and important phase of medicine.

I. L. WAINE

LITTLE new can be said concerning a work such as *A Textbook of Histology* by Jordan which is so well established among those modern textbooks of human histology designed especially for medical students. Since the first appearance of Professor Jordan's text there have not been any radical changes from edition to edition although during the years there has been a definite steady trend toward improvement. Especially is this true of the illustrations which in the current edition show 30 meritorious replacements. On the other hand the present volume contains so few textual alterations that the subject matter as a whole cannot be said to have been seriously disturbed. One shortcoming of the preceding edition was its bulky size and burdensome weight. Considerable reduction has now been effected although this could well be carried still further without introducing any appreciable loss. Moreover one again questions the wisdom of including a section on laboratory directions and especially so when the instructions are so individualistic as to be of no real usefulness outside the author's own course. Possibly the criticism of unnecessarily adding to bulk can be directed equally against the section on histologic technique. Since these two sections total 85 pages, they add materially to a volume already overly large for convenient handling.

The number of editions run through since 1916 attests to the continued success of Jordan's *Histology*. It remains a welcome and helpful member of the tried teaching texts in this country. Though not the leader in its field it possesses many valuable features and must rate high among the more ambitious texts of medical histology.

L. B. AREY

THE *Atlas of Hematology*² was written primarily for the clinician, student and technician rather than for the hematologist. Dr. Osgood is responsible for the descriptive part of the text whereas the colored illustrations were drawn by Ashworth. The first half of the book contains 325 colored illustrations, mostly of individual blood cells magnified 2500 times. One or more illustrations of practically every known type of blood cell are included. The coloring and architecture of the cells are extremely accurate and realistic. One should experience little difficulty in identifying cells in a blood film with the use of these illustrations. General characteristics of each cell group are described along with their occurrence in health and disease. Each cell is numbered and described individually.

The author expresses a polyphyletic view of blood formation. He believes that the various specific blast

cells are not formed continuously from the reticuloendothelial system after fetal life. An entirely new nomenclature is recommended, the most radical changes being in the erythrocyte and granulocyte series. Although the reasons given for these changes are logical, such terms as rhabdocyte, lobocyte, akaryocyte, etc., can have meaning only to the unfamiliar with the atlas. Throughout the book the newer terminology is given preference but is always followed by the more familiar terminology in parentheses. As the book was written for general usage it seems that the new terminology could well have occupied a less prominent place.

Some hematologists will take exception to such views as (1) the typical cell in infectious mononucleosis is a polymorphocyte, (2) plasmocytes develop from plasmoblasts, (3) fenestrations in the lymphocytes might be the only differentiating point in the blood smear between infectious mononucleosis and subacute lymphocytic leucemia, and (4) the red cells in individual with ovalocytosis are not elliptical nor as a rule oval. Illustration No. 27 is a lymphocyte with a clover leaf shaped nucleus. The reviewer has seen this abnormality frequently in smears made from venous blood that contained too much oxalate as an anticoagulant.

The second half of the book is devoted to a rather complete description of hematologic diseases, special emphasis being given to the laboratory findings and differential diagnosis. Such chapters as (1) the differential diagnosis of splenomegaly, hepatomegaly and lymphadenopathy, (2) the differential diagnosis of sore throat and stomatitis, and (3) the hematology of infectious diseases should be of great value to the clinician. There are some minor points which are open to criticism. For example, acute hemorrhage is not considered as a cause of macrocytosis. It is stated that an idiopathic form of aplastic anemia is only supposed to occur. The dose of 3 to 6 grams ferrous sulphate daily in the treatment of iron deficiency anemia would seem rather excessive. Some of the newer literature on coagulation of the blood (e.g. prothrombin and the deficiency in hemophilia) is not included. The use of the terms, simple leucocytosis for counts ranging from 4000 to 40,000 per cubic millimeter and simple leucopenia for counts from 2000 to 14,000 is not clear.

The twenty-two tables contained in the text should be of great assistance in the identification of blood cells and in the differential diagnosis of various blood diseases. Frequent reference is made to information gained from sternal puncture and bone marrow cultures. Many original investigations are presented here for the first time.

The author is frequently dogmatic about controversial subjects. This is not objectionable as it furnishes a stimulus to the hematologist and at the same time does not detract from the clinical value of the book. This excellent atlas can be highly recommended to the clinician for solving various hematologic problems and to the student for learning the subject of hematology.

HOWARD J. AIT

¹ A Textbook of Histology, by Harvey Ernest Jordan, A.M., Ph.D.
7th ed. New York: D. Appleton & Company, Inc., 1937.
² ATLAS OF HEMATOLOGY, by Edwin E. Osgood, M.A., M.D., and
Clifford M. Ashworth, San Francisco: J. W. Stiles, Inc., 1937.

THE book¹ by Dr Courville does not conform to the usual plan of texts dealing with neurological pathology, inasmuch as a generous portion of the subject matter deals with clinical symptoms, and even treatment is suggested for some of the pathological entities which are discussed. Naturally, few authors dealing with pathology show any marked degree of interest in symptomatology, but Courville is both a neuro-psychiatrist and a neuro-pathologist, and his original manner of attack may spell the popularity of his book, certainly he has added interest for the casual reader and student.

Practically all the pathological states of the brain and spinal cord are discussed, even if briefly so. Pathogenesis is in each case well handled, and the author's personal interpretations, if not always wholly acceptable, are stimulating; the gross descriptions are more satisfactorily treated than are the microscopic findings; the matter of stains and histoneurological technique is not discussed. The fact that the book is based on the study of 15,000 autopsies is evidence of the author's wide experience and opportunity for quantitative research.

The book is well illustrated, and some of the photographs are remarkably good. However, composite pictures such as Figure 114, illustrating possible lesions due to birth injury, are confusing and through their complexity are in danger of losing their graphic appeal to the student for whom they were probably intended. Figures 119 and 137, the author's own drawings to illustrate histological changes, are examples of a book-wide plan of illustration which could have been more favorably shown either by good photomicrographs or a simpler form of line drawing.

The spaces allotted to a discussion of trauma to the head, brain tumors, and degenerative and infectious brain disorders are proportionate to one another and to the rest of the book except for the spinal cord. The treatment of the spinal cord in general is too brief compared to the importance of cord disease, and the student may be impressed that cord pathology is not as common as it actually is, and that its manifestations are less dramatic than is actually the case. And here one might ask, why do texts treat of pathology of the central nervous system only? Why is the pathology of the peripheral nerves in this mechanical era with its frequent nerve injuries of so apparent little interest to the pathologist?

The author seems not to be impressed by the rôle of local vertebral osteomyelitis in the etiology of spinal epidural abscess, his explanation is the common one either by direct extension from a local soft tissue lesion (as furuncle) or by the metastatic route. Cranial osteomyelitic foci (as infected mastoids or sinuses, traumatic osteomyelitis) are described, however, as being a common cause of cranial extradural abscess. He deserves much credit for his remarks on syphilis of the central nervous system,

and he is obviously annoyed by the loose term "CNS lues." In his entire series of 15,000 autopsies only six gummas of the brain were found, and it is his opinion that if syphilis is present in the central nervous system it can be detected and the particular form of the disease can be named, without need of its being confused with other, equally common, diseases which also affect the nervous system.

This book has the distinct advantage of being easy to read, the subjects are well organized, it is lacking in detail, and it is relatively brief. For these reasons, as well as for the unexpected appendix of 'clinico-pathologic aphorisms,' it will no doubt appeal and be useful to the student and general practitioner alike. It is likely that most clinical neurologists and neurological surgeons require a more complete and detailed treatise.

JOHN MARTIN

THE knowledge and experience of the editors and twenty-six contributing authors of *The Practitioner's Library of Medicine and Surgery*,² are a guarantee of its completeness and accuracy. Until recent years public health activities have been concerned mainly with the health of aggregations of people by the safeguarding of water supplies, sewage, food, the quarantine against infectious diseases, etc. More recently, largely through the influence of the advances in immunology there has been a change in stress to the individual. This shift in emphasis together with the increasing trend in medicine toward prevention of disease as against treatment, demands of the practicing physician a greater participation in public health. The authors appreciate this change and the added responsibility it has placed on the practitioner of medicine. To this end in Part I, "Individual Hygiene" is presented in a very informative manner, with chapters on periodic health examinations, hygiene and nutrition, hygiene of clothing, exercise and rest, excretion, air and sunshine, cleanliness, sex hygiene and personal hygiene. Part II, Group Hygiene, Part III, Community Health, and Part IV, Prevention of Specific Diseases, treat adequately the community aspects of public health and also many individual applications. The book is exceptionally free from typographical errors, arrangement of the contents logical, and writing, printing, and make-up excellent. Alike practicing physicians and those specializing in preventive medicine will find it most interesting and valuable.

A. A. DAY.

OF INTEREST to the obstetrician and gynecologist, and particularly to those members of the medical profession who attempt its utilization and interpretation, should be *The Rabbit Test*³ by Anklesaria, a small volume of 161 pages which presents in a

² THE RABBIT TEST, FOR THE DETECTION OF CHORIONIC TISSUE IN THE BODY AND THE DETERMINATION OF ITS PROLIFERATIVE ACTIVITY. By S. B. Anklesaria, M.D. (Bom.) With a foreword by Dr. Emil Novak. Bombay, India: Bombay Fort Printing Press, 1937. (Obtainable from H. K. Lewis & Co., Ltd., London.)

³ PATHOLOGY OF THE CENTRAL NERVOUS SYSTEM, a Study Based upon a Survey of Lesions Found in a Series of Fifteen Thousand Autopsies. By Cyril B. Courville, M.D. Mountain View, Calif.: Pacific Press Publishing Ass., 1937.

very complete manner all phases of this biologic test. The opening chapters provide a comprehensive background of such knowledge of obstetric and gynecologic endocrinology as is either necessary or available at the present stage of development. An extensive review of the literature incorporated throughout the volume serves to illustrate and emphasize the results obtained. Numerous case reports are included as the various phases of the test are discussed which adequately illustrate and support the conclusions formed. The pitfalls of erroneous interpretation due to the limitations of the test are constantly stressed by the author although it might be suggested that the respective advantages and disadvantages of the immature as opposed to the mature rabbit as the test animal have not been sufficiently emphasized. Experience has indicated that careful consideration of these factors permit the elimination of many addi-

tional sources of error. In the closing chapters the author presents a highly commendable personal contribution consisting of a technique for quantitative hormonal estimation for the differentiation between normal and abnormal chorionic development as encountered in hydatid mole and chorion epithelioma. The evidence presented indicates that the criteria suggested by the author regarding the interpretation of these determinations should reduce to a minimum the unnecessary evacuation of normal uterine contents and the removal by hysterectomy of uteri containing normal products of gestation as has so frequently occurred when haphazard dilution methods have been utilized. The author is to be commended for a very complete presentation of a difficult subject which will be of unlimited value to anyone interested in the problems involved.

NUMBER 2A

THE SURGEON AS A BIOLOGIST

J. P. LOCKHART-MUMMERY, F.R.C.S. (Eng.), London, England

TODAY surgery may be said to be truly international; it has no country and no language of its own, and the American College of Surgeons, with that insight which has always distinguished its founders, has, I consider, done more than any other single body of men to bring all nations and peoples into a common brotherhood for the furtherance of our science and craft and to foster that spirit which works for the benefit of all humanity, and not for any single section. One must hope that the day may yet dawn when, urged by the same lofty principles, the nations of the world will combine to ensure for human beings a stable political world where peace is more or less assured and is no longer a mere interval between successive wars. Science and medicine cannot progress or flourish unless there is security and peace between nations, and the same is true of all useful human enterprises and movements for betterment of the race.

The science of biology is the study of living organisms, the manner in which they arise, the way in which they function, and the methods by which they reproduce themselves. It includes such different subjects as botany, zoology, physiology, pathology, and genetics, and a biologist is one who studies living organisms and strives to discover the truths of life and living things, and in that respect every

doctor, who is anything more than a mere craftsman, may legitimately claim to be a biologist, since in his daily work he is constantly called upon to study and observe the most complicated and intricate of all living organisms, the human body.

We may take pride to ourselves that many of the greatest discoveries of the past in the biological field have been made by doctors as the direct result of their observations of the human body in the course of treating patients. I have only to mention Harvey's discovery of the circulation of the blood in the early part of the 17th century, Lister's discovery of the causes of suppuration and the way in which sepsis in wounds can be prevented, Jenner's observation that milk-maids did not contract small-pox and his deductions from those facts which led to the discovery of vaccinia, John Hunter and his intensive search for the fundamental causes of disease and injury, Cushing and Horsley's observations on the functioning of the human brain, and Banting's discovery of the cause of diabetes.

It may be said that every operation a surgeon performs is a biological experiment and affords, or may afford, an opportunity for the discovery of some new biological truth. It is, I think, often not realized by the pure laboratory research workers that unrivalled opportunities are afforded to the surgeon for direct observation of living human tissues, both in health and disease, and for the study of the

Oration on Surgery presented before the Clinical Congress of the American College of Surgeons, Chicago October 25-29, 1937

manner in which such tissues react to trauma and other forms of damage

The surgeon habitually, as part of his daily work, performs vivisection upon the human body, and in that respect has an advantage over the pure research worker, who is necessarily confined to the vivisection of animals. It is true the surgeon cannot experiment in the strict sense, but he has great opportunities of observation and a great deal of our knowledge of living processes is founded upon the accumulated observations of surgeons while performing operations upon living subjects.

We are accustomed to distinguish between pure research and clinical research, but there is no hard and fast line to be drawn between them and the clinician, provided he has the true scientific mind, is as much a pure research worker as he who works in a laboratory. The one is indispensable to the other and the best results are obtained when the clinician and the laboratory investigator are working in close collaboration.

There is, it seems to me, a very real danger in these days that medicine may be too much divided into separate compartments. We have the physician, the surgeon, the pathologist, the pure research worker, and the biochemist, all doing their own work and often hardly aware of what is happening in each others' departments. This division of work into a number of different sections is necessary in these days, if we are to make rapid progress, and there can be no doubt is largely contributing to make medicine a true science but unless close touch is maintained between the different departments the individuals tend to become *over* specialized and too much like the machine minders of the mass production factory. The surgeon and the physician should do work in the laboratory and the pathologist, the physiologist, and the research worker should sometimes attend operations and see clinical work at the bedside. I have always made it my practice to attend in the laboratory of my hospital at least once a week and I know I have greatly benefited thereby. I am persuaded that the practice is a good one. The observations that are made in the operating theater and the laboratory are more correctly evaluated if they are frankly dis-

cussed between the surgeon and the pathologist. A fact which may to the latter appear of little importance may be of the utmost significance to the surgeon who knows its clinical bearing and vice versa.

But if the surgeon is to be a biologist in the scientific sense he must learn to make exact measurements. The essence of scientific observation is exact measurement. It has been said that doctors are not scientists because they cannot express their conclusions in figures. In the past this criticism was to a large extent true, morbidity was stated as the opinion of an eminent person unaccompanied by any kind of data, and was often accepted as fact, but in recent years a great deal has been done to obtain exact data in relation to diseased and abnormal states, and medicine is on the way to becoming an exact science where proof will take the place of opinion.

We can now estimate the state of the damaged heart in terms of the electrocardiograph, the condition of the kidneys in terms of the blood urea, and the water balance of the tissues in terms of the calcium content. It is now often possible to express pathological conditions in percentages and figures.

Neither the surgeon, nor the pathologist should ever cease to learn new facts or new interpretations of old facts. The art of healing has not yet reached any finality, nor is it likely to do so for a very long while. Surgeons have from time to time fallen into the error of believing that their craft had reached such a stage of perfection that little further improvement was possible.

Even that great surgeon of the seventeenth century, Ambrose Paré, fell into the common error of ceasing to be a humble student of nature and becoming too satisfied with what he had achieved, as is evident from this passage in the dedication of his work on surgery to King Henry the Third of France: "For God is my witness, and all good men know that I have now laboured fifty years with all care and pains in the illustration and amplification of Chirurgery and that I have so certainly touched the mark whereat I aimed that antiquity may seem to have nothing wherein it may exceed us, beside the glory of invention, nor posterity anything left but a

certain small hope to add some things, as it is easy to add to former inventions." Paré was undoubtedly the greatest surgeon of his age, but were it possible for him to come back to practice today, he would find that the only thing he knew would be how to reduce a dislocation and how to set a fracture, and even in this respect he would be unable to compete with the most junior house surgeon at one of our big hospitals

This quotation from Ambrose Paré shows how unwise it is for us ever to assume that what we regard as the great achievements in knowledge and practice of our own time are final or unsurpassable, or that we ourselves have learned all that we can. Nothing is ever final, nor can knowledge ever stand still. The true enquirer, and the true surgeon, must always keep a humble spirit, content to help forward to the best of his ability the practice of his craft in his own time and in the sure hope that those who come after him will find the foundations upon which they desire to build are firm and sure, and have not, as the result of his mistakes, been falsely laid. He must be ready to unlearn much that he has learned and start again from the beginning, not once, but many times.

The changes which have taken place in the practice of surgery even in the comparatively short period since I first became a medical student at Cambridge have been very considerable. Thirty years ago, once an operation had been decided upon, the surgeon proceeded to perform it without any further assistance than an anesthetist and a house surgeon. No preparatory treatment was deemed necessary and the surgeon was quite prepared for the fact that for many hours, sometimes days, after the operation his patient would be violently sick, due to the ether or chloroform, which were the only available anesthetics. But today the surgeon requires a regular team of assistants if he is to do first class work. Often elaborate tests have to be made requiring the assistance of skilled scientists, a physician's report on the functioning of the patient's various organs has to be obtained, biopsy specimens have to be reported upon by a skilled pathologist, and the surgeon has to rely upon a number of persons beside himself

to assist him in bringing the case to a successful conclusion; in other words, the best surgery now requires team work.

This is now generally realized and is a great tribute to the pioneer work of the Mayo brothers, who first instituted it. One of the results of this development is that much more elaborate equipment for hospitals has become a necessity and that operations cannot now be satisfactorily performed in the patient's own home. Another result is that operations have tended to become more expensive, but any extra expense is well worth the additional safety that is provided by modern team work and modern hospitals.

Admirable as this is, it has always seemed to me there is today a real danger that the young surgeon who is just starting his career may too readily believe that surgical operations can be performed *only* under circumstances where such services are available, that he may come so to rely upon the facilities which a modern up-to-date hospital, like those I have seen in this city, affords, that he will be unable to operate successfully under circumstances where they are not available. But it may well happen that he will not have the good fortune to become a surgeon to one of the great hospitals of this, or any other city, but may find himself in some out of the way part of this great continent, or some other continent, where he will be called upon to perform operations entirely without skilled assistants and with none of the facilities to which he is accustomed, and if he is the man he should be he will not be discouraged but will so improvise his equipment and reorganize his technique as to be able to deal successfully with the situation. Most of us who had to attend to the wounded during the last war had to learn this lesson, and on the whole, if the results were not as good as we had expected, they were not too bad.

Some years ago I had to go to Nepal, which lies between British India and Tibet, to operate upon the Maharajah of that State, and while I was there I was asked to do a number of operations under circumstances to which I was quite unaccustomed. There were no nurses at all, the patients just "stayed put." if I may use that expression, until I

came back, often several days later. They did not seem to have moved at all since I had last seen them, although no doubt they had been fed. The anesthetists were worse than untrained, they were definitely unsafe, even when giving chloroform, which was the only anesthetic they knew anything about. I managed, however, to perform a large number of operations with, I am thankful to say, excellent results.

While modern methods are a great improvement and are essential if we are to attain to the standard we have set ourselves, namely one hundred per cent success, a great deal of excellent work can nevertheless be attained without them. The best surgeon is not he who can get good results only when working as part of a team in a modern hospital, or who cannot make a diagnosis without a pathological report, but he who can adapt himself to the circumstances in which he finds himself and still make a diagnosis and operate successfully with the minimum of risk and postoperative discomfort compatible with the circumstances.

Every surgeon who is scientifically minded, and I have little use for the surgeon who is not so minded, must be content to try to add something to the sum of human knowledge. To be content to practice his craft just as he has been taught it and to leave it as he found it should not be enough. He should strive to add something for future generations.

It takes a long time to establish the truth of new biological discoveries and only those who are content to wait and are able to put up with constant discouragement and disappointment are worthy to call themselves biological explorers. New truths take time to become established and old customs and old ideas die slowly and with much difficulty, but, in the end, truth can never fail to succeed, and to find its proper place. It may be and often is delayed, but it cannot be entirely or permanently suppressed.

Today the surgeon is making more and more use of biological research to assist him in saving the lives of his patients, or in enabling him to avoid procedures which he knows may jeopardize his results. Our recently acquired knowledge of some of the facts with regard to

the water and calcium balance of the blood and tissues has proved of the utmost value in dealing with cases of severe intestinal obstruction and in avoiding complications after certain operations. We now have tests such as the "urea clearance test" (Van Slyke test) by which we can often estimate before operation the dangers to which our patient will be exposed and which enable us to so prepare him that the risk can be much diminished or avoided. Operative surgery is gradually becoming a science as well as a craft, and those of you who will be performing operations during the next 30 years will, if you make proper use of it, have at your disposal the means to reduce many of the risks of surgical procedures that are not available to us today.

At the beginning of this century postoperative surgical shock had taken the place of sepsis as the chief cause of death after surgical operations. A certain degree of shock was expected after all major surgical procedures and the notes of that time revealed it as the most common cause of postoperative mortality. Practically nothing was then known about the cause or physiology of the condition and the treatment was confined to keeping the patient warm and injecting strychnine in large doses. It is now quite obvious that many other conditions, not then known about, were either confused with cases of true shock, or were mixed up with it. Such conditions as dehydration, calcium deficiency, what is often called acidosis, and many other now well recognized complications, were at that time not distinguished from true shock.

Looking back upon my early days at the Queen's Hospital for Children, I remember many postoperative deaths among the children in my surgical wards that I now recognize as having been due to acidosis caused by the chloroform then used as an anesthetic, and which could easily have been prevented by the administration of sugar or alkalis, had we at that time known what to do.

The commonly accepted pre operative treatment at that time was to administer a smart purge to the patient the day before the operation and to starve him for 12 hours. After the operation water was given in teaspoonful doses and no food allowed for several days.

When we realize that as a result of the use of the anesthetics then in vogue severe vomiting was the rule rather than the exception after any operation, it only surprises me when I look back to those days that our mortality was not worse than it was, but even then our patients often insisted on recovering despite our efforts! The general principle of treatment in those days appears to me to have been that anything the patient desired *must* be bad for him and should, therefore, be withheld!

It was then that Dr. Crile first published his famous monographs describing the results of his research work into the causes of surgical shock. At about the same time I was carrying out research on the same subject in England, and in 1905 I had the honor of delivering the Hunterian Lectures at the Royal College of Surgeons in England on "The Cause and Prevention of Shock."

I was a follower of Dr. Crile's in that I believed exhaustion of the nerve cells controlling the vasomotor centers, from overstimulation by ascending sensory stimuli, was the primary and essential cause of the condition known as "surgical shock." For a time this theory held the field and was to a large degree accepted as the correct explanation of surgical shock, though it met with considerable opposition both here and in England. But in 1917 when my old schoolfellow, Sir Henry Dale, discovered histamine, opinion began to change. In 1919 when he and Laidlaw propounded the theory that surgical shock was due to a toxic agent (histamine) liberated by trauma of the tissues, opinion swung round to the belief that surgical shock resulted from chemical poisons circulating in the blood as the result of the trauma.

Whether the theory of exhaustion of the nerve centers put forward by Dr. Crile and myself over 30 years ago is correct or not is still unsettled, but I think you will agree with me that the value of any biological discovery must be considered in relation to the benefits to humanity that result: in fact this might be considered a useful "yard stick" for measuring the value of any advance in knowledge. Now, there can be no question that the theory of shock being due to exhaustion of the vasomotor centers led directly to the application of

methods in prevention and treatment which have in recent years almost entirely eliminated surgical shock as an operative risk. I can frankly say that I cannot recollect a single case of true surgical shock having come under my observation during the last 15 years, and that is not because surgical operations have become less drastic or less formidable than previously, for the reverse is the case.

Whether this theory of the exhaustion of the nerve centers is the correct one, or not, future biologists will no doubt eventually decide, but the benefits to humanity of the publication of the theory have already been reaped. It is interesting to observe in this connection that quite recently the biologists and physiologists have shown a tendency to swing over again to our original theory of nerve exhaustion.

No one has been able so far to detect any substance in the blood coming from a traumatized limb which will cause shock when injected into another animal. Also Simonart has shown experimentally that if the vessels of a traumatized limb are occluded prior to the trauma but the nerve supply left intact, a typical condition of shock develops, although there is no blood passing from the traumatized limb to the general circulation. It looks, therefore, as if the original theory of nerve exhaustion is in the main correct. In any case I feel sure that Dr. Crile, like myself, will be content to leave the truth to be established in the lap of time.

A new branch of biology which has recently engaged the attention of scientists throughout the world is destined, in my opinion, to have a profound influence upon medicine and surgery in the near future. I refer to the science of genetics, the means by which heredity works to transmit characteristics from the parent to the offspring. At first it may seem that this has little to do with the healing art, but it is generally recognized that it is as much the duty of doctors to prevent disease as to cure it and anything which will assist us to understand how diseased conditions arise, or are transmitted from one generation to another, will better equip us to combat them.

There is much yet to be discovered in the field of human genetics, but thanks largely to

the brilliant work of Morgan, de Vries, Muel-
ler, Loeb, Maud Slye and their co workers, a
great deal has already been discovered

In the science of genetics, which may be
defined as the manner in which hereditary
characteristics are transmitted from parent to
offspring, we have, I believe, found the key
which will open that door, so long closed to us,
behind which is to be found the explanation
of the cause of tumors. Ever since human
diseases began to be studied scientifically in-
stead of empirically the chief problem that
has intrigued everyone has been that of the
origin of tumors. A vast amount of time and
money has been spent during the last 25
years in attempting to elucidate this problem,
and, although no definite result has been
reached, the enquiry has been considerably
narrowed. We now know that tumors occur
in all vertebrate animals, that they are species
specific and cannot be transmitted from one
species of animal to another, that if left alone
they continue to grow indefinitely during the
life of the organism in which they arise and
that if completely removed they do not tend
to recur. We know that by selective breeding,
mice can be obtained that are predisposed
almost one hundred per cent to the formation
of spontaneous tumors, or are almost entirely
immune to the development of such tumors.

The first suggestion that tumors might be
explained by a change or mutation in the
nucleus of a somatic cell was made by Boveri
in 1914. He put forward the theory that a
mutation of the chromosomes in a somatic
cell was the cause of tumors, but when it was
found that the chromosomes in the nuclei of
human tumors were normal both in numbers
and arrangement this theory had to be aban-
doned, though it may be true of some of the
tumors of plants. Bauer had also suggested
that a mutation of the nuclear elements in a
somatic cell might be the cause of tumor
formation (1928). In 1932 I published the
theory that tumors are due to a mutation of
the genes in a somatic cell for excessive repro-
duction.

This theory has the merit of offering a satis-
factory explanation of the known facts about
tumors which no other theory has hitherto
achieved. But in order to establish a theory

it is necessary to bring forward experimental
proof, and at present this is not possible.
The genes are, and must always remain,
invisible to the human eye and gene mutation
cannot ever be visible. So far no one has suc-
ceeded in devising any form of experiment
that will prove that a tumor results from a
gene mutation in a somatic cell, and at present
the theory remains as a logical deduction from
known facts of the probable causes which re-
sult in the formation of a tumor.

A logical conclusion which explains the
known facts, even if it is no more than a stated
opinion, promotes the progress of scientific
knowledge even if it should subsequently
prove to be wrong. At present this theory
relies on negative rather than positive evi-
dence, but all the findings of Maud Slye and
others on genetic factors in mouse tumors
seem to support it.

The remarkable observation made by
McFarland and Meade on tumors in uniovular
twins seems to me strongly to support the
theory. They collected 20 reports on tumors
occurring in homologous, or uniovular, twins.
In every case the tumor was present in both
twins at the same time. The tumor was of the
same type and occurred in the same organ.
In one case both twins developed sarcoma of
the right testicle at the same age and in an-
other case both twins at the same age devel-
oped duct carcinoma of the right breast.
Since uniovular twins result from the division
of the original fertilized ovum into two
halves each of which develops into a com-
plete individual it must follow that they have
an exactly identical genetic constitution.

It seems to me that nature has here per-
formed an experiment for us which proves
that tumors are due to some genetic change
in the nuclei of certain somatic cells. We
know that variations which are permanent
and irreversible result from gene mutations
in the germ cells, and that by this proc-
ess working during millions of years, the
various species and varieties of living organ-
isms which inhabit this earth have been slowly
evolved. It seems reasonable to conclude that
similar gene mutations can also occur in the
somatic cells of the adult individual. If such
a change takes place for increased rate of

growth in a somatic cell then since the change must be permanent and irreversible the ultimate result must be the development of a tumor.

An obvious argument against this theory is that if mutations occur in somatic cells there should be many examples of this, apart from tumors, since it is unreasonable to suppose that only mutations occur which result in excessive growth. But mutations which result in any other change will never be seen. A somatic cell is not like a germ cell in having numerous progeny; when it dies it is only replaced by another single cell, and if it underwent a mutation to become black instead of white, since only a single cell would be affected, no obvious result would appear. It is only when an increased rate of reproduction is included in the mutations that any result can become obvious.

This theory, while it appears to explain the origin of tumors, does not seem to afford any easy solution to that much greater and more important problem of how to prevent or cure tumors in human beings, but knowledge is strength and human experience seems to show that when the cause of a disease is known it has generally led to the discovery of some means of prevention or cure, and it may well be that tumors will prove no exception.

I hope that my oration this evening has demonstrated that the surgeon should also be a biologist, that he should not be satisfied merely to practice his craft with dexterity and success, but should strive to make use of his unrivalled opportunities for the observation of human processes in health and disease, to learn new truths, however apparently un-

important, which when checked and rechecked may in the course of time add to the sum of human knowledge and lead in the future to better and surer means of alleviating human suffering.

TREATMENT OF PEPTIC ULCER—INDICATIONS FOR SURGERY

J H MEANS, M D, Boston Massachusetts

SINCE the chairman of your Board of Regents has insisted that I a mere physician, speak to you, a group of surgeons, on the indications for surgery in peptic ulcer, although I assured him I had nothing new or original to contribute to that time honored subject, I am constrained to believe that he feels that the physician's as well as the surgeon's opinion on when the patient with ulcer should undergo operation, is important. Certainly it is true that in most instances it is the physician who first sees the patient with ulcer, makes the diagnosis, and decides whether or not to call in the surgeon. Moreover, if the surgeon is called in and operates, the physician will still have to care for the patient for the rest of his life because surgery (8, 11) usually does not cure the patient with ulcer any more than does medicine. As a physician approaching the problem of indications for operation in peptic ulcer I may ask, "What can the surgeon do for my patient which I cannot do, and what are the risks, complications, and sequelae of the kinds of treatment which he can furnish? How permanent is the relief he can give?" If answers to these can be found the problem raised by the title will be solved.

The etiology of peptic ulcer (12, 17, 20, 28, 36, 37) is unknown, nor does speculation as to etiology give any aid at the present time to choice of treatment. For our immediate purpose it is only necessary to accept as fact that ulcerations commonly occur in stomach and duodenum, occasionally in the esophagus and in the small bowel, as a result of surgery, and that they produce certain typical, or some times atypical, symptom pictures and run certain characteristic clinical courses. One of the most important features of a peptic ulcer is that although it tends to heal, it also tends to

recur or become chronic (11). As either physicians or surgeons, we may relieve the symptoms of ulcer, or alter its course. We have yet to learn how to remove the cause of the disease.

Before planning treatment in ulcer it is necessary to determine beyond peradventure whether an ulcer be truly present, and, if so, of what variety. In the diagnosis of ulcer careful history taking, expert roentgenography, and of late gastroscopy, are all important. Physical examination usually yields comparatively little direct evidence, and analysis of gastric contents is less important than it used to be because other procedures give more significant information. On the whole the diagnosis of ulcer is rather accurate (40). Not only is it important to discover the presence of ulcer, but also its location because location conditions its course, and is importantly related to indications for treatment.

Gastroscopy rates special mention. It is not a substitute for x ray, rather an adjunct, but, by means of the direct view it affords, a more accurate impression of the nature of a lesion can often be obtained than is possible in any other way. It is of vast importance in determining the source of hemorrhage in certain cases, of gastritis, for example, in which there may be bleeding approaching in magnitude that in ulcer. The introduction in 1932 of the Wolff Schandler flexible gastroscope (34) revolutionized gastroscopy, because it converted a dangerous procedure into one which is quite safe provided certain simple precautions are taken, and one not attended by great discomfort. In the hands of Benedict (6, 7) at Massachusetts General Hospital who, I think, was the first to use the instrument in this country, gastroscopy has become an important aid to our diagnostic equipment. Edwards, in England has reported results quite similar to Benedict's.

The differential diagnosis between ulcer and cancer is the most important, in this field which we have to make. First symptoms com-

From the Medical Services, Massachusetts General Hospital and the Department of Medicine, Harvard Medical School.
Presented before the Clinical Congress of the American College of Surgeons, Chicago, October 25-29, 1937.

ing on acutely in middle life, or later, of course strongly favor cancer, although even so they can be due to ulcer. More often the problem is not so much one of distinguishing between ulcer and cancer as in determining whether the patient with known chronic ulcer also has cancer. The gastroscope gives important aid in settling this question.

The location of the lesion is of vast importance in the cancer question. A lesion which can be clearly placed in the duodenum is almost certainly not carcinomatous. A lesion of the greater curvature of the stomach is almost certainly malignant; so too is one high in the fundus. An ulcer in the prepyloric region of the stomach or upon the posterior wall is to be looked upon as cancerous until proved not to be. Lesser curvature ulcers are usually not malignant, but even they may be. In the case of lesser curvature, prepyloric or posterior wall gastric ulcers not definitely cancerous by x-ray and gastroscopy, and with constitutional symptoms suggestive of cancer lacking, it may be permissible to observe the effect of a short course of strict medical regimen, including rest in bed, upon symptoms and x-ray and gastroscopic findings (19). If, after not more than a month of such treatment, cessation of symptoms and unmistakable evidence of healing by x-ray are not obtained, then exploration without further delay should be recommended. If, on the other hand, convincing evidence of healing is obtained, expectant treatment may be carried further, but even then re-examination by x-ray should be made at rather frequent intervals. Exploration should be urged at any time when healing is not progressing.

Having made a diagnosis of ulcer and determined its location and ruled out cancer, to plan treatment intelligently it next becomes necessary to consider the following questions: Is the ulcer acute or chronic? Is it penetrating or perforating? Is it bleeding? Is it causing obstruction? In brief, is it simple or complicated? Upon the answers to these questions and upon location of the lesion will rest the decision of whether the given patient is to be treated by medicine alone or by a combination of medicine and surgery.

There is theoretical ground for claiming that all cases of peptic ulcer should be treated

surgically, that the surgeon can remove *in toto* all the ulcer bearing regions, and that only in this way can the disease be truly cured. The actual results of surgery thus far do not justify any such position. The statistics available in the literature indicate that the results in large series of medical treatment alone or medical plus surgical are not very different (11, 25, 40). It also is evident that the risk of operation is far from negligible.

This being true, it seems fair to say that aside from the occasional diagnostic necessity of exploration, which I have mentioned, surgery is indicated in peptic ulcer only for certain complications and for resistance to medical treatment (11, 17, 26), or for failure of previous surgery, nor is it clear that it is always indicated even then. The experience at the Massachusetts General Hospital indicates that about 10 per cent of all patients with duodenal ulcer ultimately come to surgery, but that 30 to 40 per cent of those with gastric ulcer come to operation. We can distinguish perhaps between certain absolute indications for surgery and others which are debatable.

The most absolute and urgent indication for operation is perforation. Although patients on occasion have undoubtedly survived perforation without surgery, the physician's job after making, or indeed suspecting, the diagnosis of perforation is to send at once for the surgeon. It is generally agreed that the prognosis gets steadily worse as time elapses; therefore one can say that the longer the physician remains inactive in such a case the more subject to criticism he becomes (32).

The operation to be done has the immediate purpose of closing the perforation and of saving the patient from death from peritonitis. There are some who advise going further at the same time and performing an operation designed to modify the course of the ulcer as well as simply to close the hole. Routine gastro-enterostomy, for example, with perforation closure, has been advocated, and even routine partial gastrectomy. At the Massachusetts General Hospital most of us agree emphatically with Graham, with Guthrie and Sharer, and with others (33), that to subject a patient in as imminent danger of death from

shock as is one with a perforated peptic ulcer, to the hazard of more than the minimum surgery necessary to correct the acute situation, is not wise treatment. Only the double complication of perforation and marked obstruction should justify more than simple closure. The preparation of the patient with perforation must be rapid but thorough. Transfusion to correct or to prevent shock is often indicated. The imminence of shock depends upon the time elapsing between perforation and operation, and upon the condition of the patient prior to the perforation. If operation is carried out within a few hours of perforation, because of the relatively sterile nature of the material spilled into the peritoneal cavity, drainage is usually unnecessary. It is very desirable to avoid drainage if possible, because the adhesive process, which it will surely set up, greatly increases the likelihood of obstruction later (18). In patients under care for chronic ulcer, it should be possible to minimize the occurrence of perforation. By strict attendance to the nature of symptoms and x-ray and gastroscopic evidence, one may detect and deal with penetration before it results in perforation rather than after.

Let us next consider the complication of hemorrhage. The indications for operation here can by no means be settled as easily as in the complication of perforation. Surgery is always indicated in perforation unless the patient be so near moribund that there is no hope of saving him. The only debate concerning indications for surgery in perforation has to do with how extensive the surgical procedure should be. In the case of hemorrhage not only is there difference of opinion as to when and what operation is to be done, but also whether operation is indicated at all. Perusal of the papers of Allen, Gordon Taylor, Tidy (39), Finsterer, Graham Hurst, Hinton, Goldman, Meulengracht Schudt and Woldman will give the reader a vivid impression of the divergence of opinion as to how hemorrhage from peptic ulcer should be treated. To arrive at a reasonable solution of the problem it is necessary to recognize that hemorrhage occurs under a variety of circumstances having different therapeutic significance. There are large exsanguinating hemorrhages there

are small ones carrying little risk. There are first hemorrhages and recurrent hemorrhages. There are hemorrhages in young persons and in old. All these factors have to be taken into consideration in planning treatment.

It is the opinion of Allen, Jones, and others at the Massachusetts General Hospital, that the factor of age has not been sufficiently stressed. First hemorrhages from peptic ulcer in persons under 50, even though massive rarely cause death. It seems to us very doubtful if operation during hemorrhage is indicated in such cases. Nor does it seem to us that subsequent operation in the case of first hemorrhage done for the purpose of preventing further hemorrhage is rational. There is a fair chance that the patient will never have another hemorrhage, even if not operated upon, and there is no guarantee that he will not have one again if operation is done.

In the treatment of massive hemorrhage from peptic ulcer whether first or recurrent, one of the most important therapeutic measures is the slow drip transfusion (27). Transfusion is of prime importance, not only in restoring blood volume and hemoglobin concentration during hemorrhage, but also in shortening the convalescence from blood loss afterward. The drip method makes it possible to give a maximum amount of blood with a minimum risk of increasing hemorrhage by raising blood pressure.

In persons past 50 the problem is different. In them the chance of death from an exsanguinating hemorrhage is much greater. Since if checking of bleeding by surgery is to be life saving it must be done early, it has been our policy to advise operation in patients past 50 with severe hemorrhage who show no improvement with drip transfusion in from 12 to 24 hours. We believe that although this course is hazardous it gives the patients in question the best break possible. In advising operation in any bleeding case the physician should recognize that it is difficult surgery. Hemostasis in either stomach or posterior wall of the duodenum which is where most big duodenal hemorrhages come from requires a thorough knowledge of the source of the blood supply to the region and how it can be reached outside the inflamed area.

Recurrence of hemorrhage also increases the indication for surgery. As the mortality from hemorrhage rises with age, so too it does with each recurrence (2, 15). We should prefer to have operation done after hemorrhage has ceased, rather than during, although on rare occasions one might be forced to the latter. Even in persons under 40 we should favor surgical intervention if the patient had had several large hemorrhages. If it were known that the ulcer was a posterior wall duodenal, the indications for operation would be especially great. The operation of choice in patients who have bled repeatedly from ulcer is probably some sort of resection (5, 13, 17, 21). Gastro-enterostomy offers relatively little because hemorrhages are about as frequent after it as without, either from the original ulcer or a subsequently forming gastrojejunal one.

Pyloric obstruction when permanent, that is to say, not due to temporary causes such as spasm or edema, is a strong indication for surgery—whether gastro-enterostomy or gastric resection is for the surgeon to decide. It should be recalled that the patient with obstruction is often a very poor operative risk on account of the interference with nutrition which he has sustained (4, 20, 23, 24, 31, 36). He may be short of vitamins, glycogen, protein, and salts. His plasma protein may be dangerously low. Prior to operation it is very essential that every effort be made to correct any such faults. A high vitamin intake is indicated, and to restore low plasma protein transfusion is the most effective procedure. The preparation for operation in these cases is quite as important as the operation itself. In a few very malnourished patients a jejunostomy for feeding may be desirable before the surgical attack is launched at the obstruction.

Finally we come to the question of indications for surgery in cases when adequate medical treatment has failed to give satisfactory relief. I may say also at this point that adequate medical treatment is not a matter of dietary regulation and rest alone. The psychic state of the patient with ulcer, as physicians and psychiatrists have found out, is of great importance (9). Peace of mind promotes peace and healing in a peptic ulcer perhaps more than any other factor. Persons who work un-

der strain, as for example surgeons, often have ulcers, and the more their jobs harass them the more their ulcers plague them with symptoms. Cases resistant to medical treatment will include many of the posterior wall duodenal ulcers which have become penetrating and involved neighboring structures. When this has happened, and its happening may be indicated by change in character and severity of symptoms, operation is undoubtedly indicated. What operation should be done has to be settled in the individual case (14, 26, 38). Whereas gastro-enterostomy in duodenal ulcer gives immediate relief to symptoms in many cases, it is far from ideal because of the frequency, perhaps 15 per cent of cases, in which it is followed by jejunal or gastrojejunal ulcer. It is particularly unsuitable in persons with hyperacidity and hypersecretion, and in those who have no pyloric obstruction. In cases in which gastro-enterostomy has been done, sustained and thorough supervision is indicated in order that postoperative ulceration can be detected early, as both hemorrhage and perforation not infrequently result from it (41). When jejunal or gastrojejunal ulcer is established, further operative closure of the gastro-enterostomy combined with such resection as is indicated becomes necessary.

Lesser curvature gastric ulcer will also sometimes fall in the group in which surgery must be done for intractability. The operation of choice in these is undoubtedly resection (partial gastrectomy), but occasionally in older patients, in highly weakened states, prudence demands the election of gastro-enterostomy instead.

CONCLUSIONS

In conclusion I will give as my opinion that all patients with peptic ulcer must be treated medically from the time the diagnosis is made until the end of their lives; that in addition, for certain complications of ulcer, surgical treatment will have to be employed.

The absolute indications for surgery are in the treatment of the complications of perforation and organic obstruction and to rule out cancer. The indications for operation about which opinion differs most greatly are those concerning hemorrhage. Personally, I shall accept the view that operation should be

shock as is one with a perforated peptic ulcer, to the hazard of more than the minimum surgery necessary to correct the acute situation, is not wise treatment. Only the double complication of perforation and marked obstruction should justify more than simple closure. The preparation of the patient with perforation must be rapid but thorough. Transfusion to correct or to prevent shock is often indicated. The imminence of shock depends upon the time elapsing between perforation and operation, and upon the condition of the patient prior to the perforation. If operation is carried out within a few hours of perforation, because of the relatively sterile nature of the material spilled into the peritoneal cavity, drainage is usually unnecessary. It is very desirable to avoid drainage if possible, because the adhesive process, which it will surely set up, greatly increases the likelihood of obstruction later (18). In patients under care for chronic ulcer it should be possible to minimize the occurrence of perforation. By strict attendance to the nature of symptoms and x ray and gastroscopic evidence, one may detect and deal with penetration before it results in perforation, rather than after.

Let us next consider the complication of hemorrhage. The indications for operation here can by no means be settled as easily as in the complication of perforation. Surgery is always indicated in perforation unless the patient be so near moribund that there is no hope of saving him. The only debate concerning indications for surgery in perforation has to do with how extensive the surgical procedure should be. In the case of hemorrhage not only is there difference of opinion as to when and what operation is to be done but also whether operation is indicated at all. Perusal of the papers of Allen, Gordon Taylor Tidy (39), Finsterer, Graham, Hurst, Hinton, Goldman, Meulengracht, Schödt and Woldman will give the reader a vivid impression of the divergence of opinion as to how hemorrhage from peptic ulcer should be treated. To arrive at a reasonable solution of the problem it is necessary to recognize that hemorrhage occurs under a variety of circumstances having different therapeutic significance. There are large extravasating hemorrhages there

are small ones carrying little risk. There are first hemorrhages and recurrent hemorrhages. There are hemorrhages in young persons and in old. All these factors have to be taken into consideration in planning treatment.

It is the opinion of Allen, Jones, and others at the Massachusetts General Hospital that the factor of age has not been sufficiently stressed. *First hemorrhages from peptic ulcer* in persons under 50, even though massive, rarely cause death. It seems to us very doubtful if operation during hemorrhage is indicated in such cases. Nor does it seem to us that subsequent operation in the case of first hemorrhage done for the purpose of preventing further hemorrhage is rational. There is a fair chance that the patient will never have another hemorrhage, even if not operated upon, and there is no guarantee that he will not have one again if operation is done.

In the treatment of massive hemorrhage from peptic ulcer whether first or recurrent one of the most important therapeutic measures is the slow drip transfusion (27). Transfusion is of prime importance, not only in restoring blood volume and hemoglobin concentration during hemorrhage, but also in shortening the convalescence from blood loss afterward. The drip method makes it possible to give a maximum amount of blood with a minimum risk of increasing hemorrhage by raising blood pressure.

In persons past 50 the problem is different. In them the chance of death from an extravasating hemorrhage is much greater. Since, if checking of bleeding by surgery is to be life saving it must be done early, it has been our policy to advise operation in patients past 50 with severe hemorrhage who show no improvement with drip transfusion in from 12 to 24 hours. We believe that although this course is hazardous it gives the patients in question the best break possible. In advising operation in any bleeding case the physician should recognize that it is difficult surgery. Hemostasis in either stomach or posterior wall of the duodenum which is where most big duodenal hemorrhages come from requires a thorough knowledge of the source of the blood supply to the region and how it can be reached outside the inflamed area.

TECHNICAL SURGICAL PROCEDURES FOR GASTRIC AND DUODENAL ULCER

ROSCOE R. GRAHAM, M.B., F.R.C.S.(C.), Toronto, Ontario

THE honor which you have conferred in asking that we present our experience in the operative treatment of peptic ulcer is deeply appreciated. Our remarks are based upon the cases studied and patients operated upon from July 1, 1929, to September 1, 1937, on the First Surgical Division of the Toronto General Hospital.

Dr Means has presented to you the problems involved in the treatment of individuals with ulcer. He has also outlined the indications for surgical therapy. Today there is no fundamental disagreement between the physician and surgeon in the management of patients suffering from peptic ulcer. Surgical procedures have no place in the treatment of simple duodenal ulcer, and should be carried out for gastric ulcer only after adequate non-operative therapy. Operation, therefore, becomes necessary only in dealing with the complications of perforation, obstruction, penetration, and recurring hemorrhage. It is necessary to follow only a few patients suffering from the complications of an ill-advised, badly chosen, or technically faulty operative procedure, to be impressed with the great responsibility the surgeon must assume in advising an operation for gastric or duodenal ulcer.

The patient who accepts operation expects. (1) recovery from the operation; (2) relief from the symptoms, (3) security against recurrence of the disability; (4) restored economic efficiency.

In order to achieve this desired result, the surgeon, in determining the correct operative procedure, must take into consideration: (1) the site of the ulcer, (2) the character of the pathological lesion; (3) the associated physiological disturbances; (4) the resultant biochemical disturbances, (5) the age of the patient.

From the Department of Surgery, The University of Toronto, and the Surgical Service, The Toronto General Hospital.
Presented before the Clinical Congress of the American College of Surgeons, October 25-29, 1937.

1. *The site of the ulcer.* The site of the ulcer has a definite bearing on the operative procedure. The term "peptic ulcer" we believe to be bad. It is not used in our department. It presupposes a known cause of ulcer. It infers that gastric and duodenal ulcer are similar diseases. We believe much harm, confusion, and disastrous therapy have resulted from considering these 2 lesions as a single disease entity. We believe that in all cases we should speak of a duodenal ulcer or of a gastric ulcer, and discard entirely the term "peptic ulcer."

The difficulty of excluding malignancy in all gastric ulcers is well recognized. We have no interest in the debate as to whether a gastric ulcer becomes malignant or not. We are very greatly concerned in attempting to determine if the ulcer be malignant *now*. Such a problem does not arise in duodenal ulcer. If the lesser curvature of the stomach be divided by the incisura, our experience has shown that an ulcer situated proximal to this point is much less likely to be malignant than one situated between the incisura and the gastroduodenal junction.

In the duodenum, an anterior wall ulcer may produce severe symptoms, and be the seat of an acute perforation. If, however, the patient suffers from massive hemorrhage, we must realize that this anterior wall ulcer cannot be the source, but must be accompanied by a posterior wall ulcer. A posterior wall duodenal ulcer may be present with no anterior wall ulcer. Such an ulcer may produce no symptoms except recurring massive hemorrhage, or such symptoms as would result from a slow perforation, with the development of a peri-duodenal abscess. We have studied a series of posterior wall duodenal ulcers occupying the descending limb of the duodenum just proximal to the ampulla of Vater. Such have not given symptoms which enabled us to arrive at the diagnosis of duodenal ulcer. In

limited to patients bleeding after 50 or those having repeated hemorrhages

Resistance to medical treatment, or intractability, is a rather weighty indication for surgery, but a patient should not be branded as resistant to medical treatment until the latter has been adequate. The surgical problem in resistant cases is not so much one of whether surgery is indicated, but of what operation is best suited to the individual patient's needs. In general, some sort of resection is probably to be preferred to short circuiting procedures.

Finally, I should like to urge the closest possible co-operation between physician and surgeon in these matters. The physician should not be dismissed when the surgeon is called; he should remain in full partnership with the surgeon, both in preparation for operation and after care, and he should remain in charge of patient after the surgeon is finished with him.

there is an increase in the units of free hydrochloric acid in the stomach. The degree of hypersecretion, and the increase of free hydrochloric acid, are, in most instances, in inverse ratio to the patient's age. Thus the control of ulceration in the young individual presents a much more difficult problem, not only to the physician, but also to the surgeon, than if the patient were elderly. In the instance in which a pyloric obstruction from scar has resulted in an atrophy of the gastric glands, there is a decrease in the units of free hydrochloric acid, whereas in the pyloric obstruction due to edema, the very activity of the ulcer resulting in the edema is accompanied by hypermotility and hypersecretion, and this means an increase in the free hydrochloric acid in the stomach.

As a result of pyloric obstruction, or pain associated with the intake of food, or a restricted intake because of the dietetic regimen, various biochemical disturbances are present. Vomiting accompanying pyloric obstruction is an outstanding symptom, and the loss of body fluids or salts results in a disturbance of the acid base balance of the individual, indeed, may even result in tetany and coma. Pain or restricted diet may result in undernourishment, or secondary anemia. Restriction of physical activity results in loss of general muscle tone. Ravdin has pointed out that such biochemical upsets may be accompanied by a decrease in the serum protein.

5 *Age of the patient* From the foregoing it is obvious that whenever possible operation should be avoided in the young individual. When, however, it becomes imperative, it should be a radical procedure. In the older patient, a more conservative operation of the indirect type is more often indicated. In a series of patients followed by MacFarlane who were operated upon within 2 years of the onset of symptoms, 46 per cent had an unsatisfactory result. Most of these patients were operated upon by an indirect procedure, before self-discipline was attained. The results eloquently confirm the wisdom of our present attitude.

An operation carried out without the recognition and correction of the above disturbances leads but to disaster. Therefore any

operative procedure for a gastric or duodenal ulcer must: (1) result in a decrease in the hydrochloric acid in the stomach; (2) establish efficient gastric emptying, with freedom from spasm in the stomach or duodenum; (3) be accompanied by excision of the gastric ulcer; (4) be associated with ligation of the blood supply of the duodenum in patients suffering from massive hemorrhage from a duodenal ulcer.

If operation be undertaken for a persistent and uncontrolled gastric ulcer, believing as we do that all gastric ulcers must be excised, we must choose between a local excision with the knife or cautery, with or without an associated gastro-enterostomy, or the more radical procedure of partial gastrectomy. In our experience all operations for a gastric ulcer other than partial gastrectomy have been so frequently followed by unfortunate post-operative sequelæ, that we have abandoned them. It is possible to do a gastric resection and resect any gastric ulcer. The principle of leaving undisturbed the ulcer base, which may be on the liver or pancreas, has made this possible. We would suggest that unless the ulcer be removed, the patient is better without operation. Many clinicians will cite cases in which a simple gastro-enterostomy has cured a gastric ulcer. May we suggest that were such patients put to bed on a proper diet and treated by means of the indwelling duodenal tube, as advised by Cleaver, such ulcers would heal without the surgeon's help. The medical regimen for gastric ulcer as outlined by Cleaver in our hospital is so efficient that operation for an uncontrolled gastric ulcer is rarely necessary. Cleaver's regimen consists in the introduction of a duodenal tube, which is proved radiographically to lie in the duodenum. No food or fluid is given by mouth, but through this tube adequate nourishment and fluids are introduced, and the stomach is thus placed at rest. Roentgenograms are made at the end of 3 weeks' treatment. If the ulcer is smaller, a further 3 weeks' treatment is given. If at the end of 6 weeks the ulcer is not healed, operation is advised. If the ulcer be healed at the end of 6 weeks, further roentgenograms are taken after another 3 weeks. A recurrence at this

over half the cases, because of the location of the ulcer, x ray studies have failed to reveal their presence. Such have been recognized only after an exploratory laparotomy under taken for persistent abdominal pain, or recurring hematemesis. We have termed such ulcers *duodenal ulcer occulta*.

2 The character of the pathological lesion

The local lesion has a definite bearing on the surgical procedure in the individual case. An acute perforation may occur in an acute or chronic ulcer. In either case, simple closure of the perforation will deal adequately with the emergency, and thus discharge the surgeon's sole responsibility under such circumstances. A posterior wall duodenal ulcer by penetration may invade the pancreaticoduodenal artery, or one of its branches. Such a lesion, in our experience, has been present in cases of massive hemorrhage. Indeed, the common duct may be invaded and an infective cholangitis result because of the direct communication of the duodenum with the common bile duct through the infected ulcer base (Fig 1). A gastric or a duodenal ulcer not uncommonly invades the liver or pancreas or both. In such ulcers, as their removal is desirable if operation be undertaken, our experience has taught us that leaving the ulcer base undis turbed has made the procedure more safe and has permitted removal of the pathological lesion in cases in which, if the base itself had to be removed, the attempt would have had to be abandoned. The pathological change about a duodenal ulcer may result in obstruction with the associated phenomena. The obstructing factor may be scar or edema from the inflammatory reaction about an active ulcer. It is of the greatest importance that we differentiate these two factors. The former has been progressive over a long period, and is accompanied by an atrophy of the gastric glands. The latter is of recent onset, is not accompanied by any change in the gastric glands, and continuous gastric drainage for 7 to 10 days with an indwelling duodenal tube results in the disappearance of the obstruction. With both sources of obstruction there is edema in the gastric wall. The stomach is large, and, in the scar obstruction, often atonic.

3 *The physiological disturbances* Such disturbances associated with an active duodenal ulcer are hyperperistalsis and increased gastric secretion, together with spasm in the stomach or duodenum. In an active gastric ulcer which has not penetrated all the muscle coats, there is demonstrated radiographically an evidence of persistent spasm. This is represented by a deep contraction in the greater curvature immediately opposite the crater in the lesser curvature (Fig 2). If, however, the ulcer has penetrated all the coats of the stomach, there is no such spasm but a large defect on the lesser curvature (Fig 3).

In a recent visit to Bergland's Clinic in St Erik's Hospital, Stockholm, we were shown a pitfall in the interpretation from x ray studies of the large penetrating ulcer. In the case presented, such was the diagnosis radiographically, but with the gastroscope there was only a small ulcer in the mucosa. The contraction in the stomach wall was limited to the muscularis mucosa, and gave a radiological shadow which could only be interpreted as a deep ulcer crater penetrating all coats. That the muscularis mucosa contracts independently of the muscle wall of the stomach as suggested by Forsell, has been definitely proved by the unpublished work of S D Gordon in our department. This serves to put the surgeon on guard before advising operative procedures largely on x ray evidence. It also explains why bed rest in many instances results in the almost incredibly rapid healing of what appears to be a large penetrating lesser curvature ulcer. In duodenal ulcer the work of Wilson has shown that spasm of the duodenal cap is present during pain. The gastric hypersecretion is of importance to the surgeon in so far as it means an increase in the units of free hydrochloric acid. While the cause of ulcer is unknown it is agreed that an excess of free hydrochloric acid is an important factor in the persistence of the ulceration.

4 *The biochemical disturbances* The biochemical disturbances associated with ulcer are of great importance in first determining the type of preoperative preparation and, second, in selecting the proper operative procedure. As a result of the hypersecretion,

the ulcer and thus has lessened local infection and the likelihood of peritonitis.

Two patients died of pneumonia, and 1 patient returned 3 months later with an abscess about the duodenal stump. Following drainage of the abscess, a duodenal fistula developed, which added to the infection and was responsible for death.

This mortality is almost identical with our incidence in gastric resection for gastric carcinoma. We submit that while these patients have not carcinoma, they are equally crippled, and, having exhausted all other forms of treatment, are justified in accepting this risk, as, if they survive a radical gastrectomy, they can look forward to good health, as we have no case of stomal ulcer in our series which followed a primary gastric resection for benign gastric ulcer.

The patient suffering from a *scar stenosis at the pylorus* who has never suffered a massive hemorrhage, presents the easiest problem. The long duration of the disease results in atrophy of the gastric glands, with a low free hydrochloric acid content in the stomach. The problem in such a patient is simply the establishment of normal gastric emptying. Hence any mechanical procedure of the indirect type will accomplish this and be followed by a good clinical result. A posterior gastro-enterostomy or a Finney pyloroplasty we have found most suitable. A Judd pyloroplasty or a gastroduodenostomy, as suggested by Wilkie, have given good results in the hands of many surgeons, but in our series we have had such an incidence of unfortunate sequelæ that we have discarded them. Where *recurring hemorrhage* from a duodenal ulcer has been present, ligation of the blood supply of the duodenum is essential to prevent further catastrophe. Thus some type of gastric resection becomes necessary.

We have still to consider 3 groups of patients suffering from duodenal ulcer who must accept surgical therapy. One group is represented by patients most often over 50 years of age with a low free hydrochloric acid content in the stomach. Hyperperistalsis is not marked. No massive hemorrhage has occurred, and no pyloric obstruction is present. Persistent pain is the outstanding symptom,

Fig 1 Case No 036036. Hepatic and common bile ducts outlined by barium during the course of a barium meal examination. The lesion was a posterior wall duodenal ulcer which had perforated into the common bile duct.

and it is unrelieved by food, but may be temporarily relieved by recumbency. The second group presents identical symptoms, but with the following difference: they are most often under 50 years of age. There is a high degree of free hydrochloric acid in the stomach, and gastric peristalsis is markedly increased. The third group suffer from duodenal ulcer occulta in the posterior wall of the descending limb of the duodenum. In the 3 groups, the local lesion is a penetrating posterior wall duodenal ulcer, with marked peri-duodenitis. In the first of the above groups we believe that a Finney pyloroplasty will be followed by a result which will fulfill the patient's demands. In the small series of 15 cases which we have followed after this procedure, we have seen happy results. If, however, any undesirable postoperative sequelæ should follow such a procedure, we have not destroyed our anatomical bridges, and subsequent surgical procedures may be carried out with safety. If, however, the ulcer penetrates the common bile duct, the passage of gastric content must be entirely diverted by a gastric resection.

The second group, comprising the younger

date demands operation. In this way one is able to differentiate between the malignant and the non malignant gastric ulcer with greater security than we had previously attained. If at the end of the first 3 weeks' treatment there is not definite evidence of improvement, it is presumed that we are dealing with a malignant ulcer. On the other hand, as Cleaver has shown with this treatment a malignant ulcer may be healed to such a degree that no radiographic evidence of its presence can be demonstrated. Such a fact leads to the necessity of examining patients with the x ray not longer than 6 weeks after the ulcer is healed by this treatment. In Cleaver's series, over a long period there is only one case in which a malignant ulcer was treated as a benign gastric ulcer. There is just one exception to deferring operation longer than 3 weeks after the indwelling tube has shown improvement in the ulcer. This exception is in a patient whose first symptoms occurred after 60 years of age. We have so far failed to find a benign gastric ulcer which has not been accompanied by clinical evidence of its presence before 60 years of age. In other words, we believe that all gastric ulcers which make their appearance after 60 years of age are malignant, and the patient should be advised to have a gastric resection as soon as adequate preoperative preparation permits. It becomes obvious, therefore, that all gastric ulcers which we see are first treated by means of an indwelling duodenal tube. Even in those cases in which operation subsequently must be undertaken, this treatment is of the utmost advantage, as it results in disappearance of the edema in the gastric wall about the

ulcer, thus permitting a more efficient and safe anastomosis.

Table I shows the detail of the small group of patients operated upon for gastric ulcer.

Several worthy observations may be made in regard to this group. The total number of patients who submitted to operation during this period of time is very small, and forcefully emphasizes the efficacy of Cleaver's method of non-operative therapy. The patients accepted for operation failed to respond to the treatment, or the ulcer recurred soon after they resumed the responsibilities of life. The reason tube treatment failed in these cases is explained by the extent of the local pathological lesion, and in 8, or 22 per cent of the cases, the patients had an associated organic hour glass. In 13, or 33 per cent, the ulcer base was left *in situ* because it involved contiguous structures, notably the liver or pancreas.

It thus becomes obvious that the patient with gastric ulcer whom we accept for operation has an extensive pathological lesion in the stomach, often involving contiguous structures. Such patients present a technically difficult operative problem, and as a result must accept a relatively great operative risk, yet one must realize that operation is undertaken only when all else has failed. The future of the patient without operation is complete invalidism or early death.

In this series we had 6 deaths, or 17.1 per cent mortality. Three patients died of peritonitis. In one of these patients the condition demanded local anesthesia, and while attempting to put in a splanchnic block the ulcer became detached from the liver, leaving a base 2 by 1 inches, and the resultant opening in the stomach could not be controlled before peritoneal soiling occurred. This case is the one in which gastro enterostomy was carried out—obviously a resection would have been unwise. In the 2 other patients, edema was still present about the ulcer in the stomach wall. These cases provided the stimulus which has led us to treat all gastric ulcers primarily by Cleaver's method, even though we are reasonably certain that operation will ultimately be necessary. Such treatment results in the disappearance of the edema about

individuals with a high free hydrochloric acid content in the stomach and no pyloric obstruction, presents the most difficult problem in the surgical treatment of duodenal ulcer. Before considering any operation on such a patient we must be convinced that all non operative therapy has been exhausted. We must be on guard lest lack of self discipline and failure of the patient to follow the outlined regimen be the cause of the persistence of the symptoms. No operative procedure can obviate the necessity for self discipline on the part of the patients. Any patient belonging to this group who has not acquired sufficient self discipline

to give up tobacco and alcohol and follow a strict dietetic regimen, should not be accepted for operation.

Having decided that an operation on a patient in this second group is necessary, we must determine whether the technical procedure will be of the indirect or the direct type. The indirect type is exemplified by gastroenterostomy, gastroduodenostomy, the Judd or Finney pyloroplasty, the Devine exclusion operation, with or without Bancroft's modification of removing the pyloric mucous membrane. Our experience with gastroenterostomy since the first of July, 1929, is shown in Table II.

Three deaths occurred and all were due to a non functioning stoma. We believe this to be the result of edema about the suture line as has been demonstrated by Lewis in our department. Such patients would now be saved by an indwelling duodenal tube accompanied by suction drainage. The follow-

Patient was admitted September 4, 1937, following severe hemorrhage. Between this date and November 2, had 18 transfusions of varied volume and interval. On latter date, a high caloric diet, rich in animal protein, was given, followed by a spectacular rise in hemoglobin permitting radical gastrectomy December 6.

up of this series revealed 11 jejunal ulcers. Seven were proved by reoperation. In 4, the diagnosis is based on x-ray and clinical evidence. Such a high percentage of jejunal ulceration is not a condemnation of gastro-enterostomy; it is a condemnation of our judgment in selecting cases suitable for gastro-enterostomy. In the 11 cases in which a stomal ulcer had developed there was no pyloric obstruction, and a high free hydrochloric acid content was present on gastric analysis. We now believe that a gastro-enterostomy is unsuitable for such cases. We have carried out the Devine operation on 4 patients, and 3 jejunal ulcers developed and the fourth patient died from perforation of the pyloric stump 3 weeks after operation. Several of our colleagues have had happy results with Bancroft's modification of Devine's operation. We have had no personal experience with this procedure. We would not do any type of py-

loroplasty for a patient in this second group. Our experience with gastroduodenostomy is confined to 9 cases, and was most unhappy. One died from obstruction at the stoma, due to axial rotation of the duodenum, the result of a technical error. One patient has been reoperated upon for an anastomotic ulcer. Sir David Wilkie, who has carried out this operation on 180 patients, stated in a recent conversation that the incidence of late postoperative sequelæ had led him to question the value of this operation. Such experience has led us to consider for this difficult group of patients the more radical procedure of a gastric resection, with or without the removal of the pyloric antrum.

The opponents of any type of gastric resection for duodenal ulcer base their opposition upon the following opinions: (1) it is an unnecessarily mutilating operation; (2) it is accompanied by a high operative mortality;

Ward 636 Admission No. 6630

Fig 5 This graph records in 12 hour periods the relationship between gastric fluid intake and output. If output exceeds intake it is recorded below the zero line and if the intake exceeds the output it is placed above the zero line. This graphically shows when gastric emptying has been restored.

(3) it is followed by anemia and decreased economic efficiency, (4) it does not wholly protect the patient from the possibility of subsequent jejunal ulceration.

Our experience with gastric resection for duodenal ulcer extends over 11 years. We were in the beginning very loath to carry out a radical subtotal gastrectomy as originally advocated and practiced by Finsterer yet in all the patients upon whom we have operated, with the exception of the 4 in whom a Devine transection operation was done, section was made at the gastroduodenal junction and the whole or part of the pyloric antrum was removed. We have never practiced the operation advocated by Ogilvie of carrying out a radical gastrectomy but leaving the pyloric antrum intact. He based this procedure on the assumption that the anti-anemic factor originates in this area of the stomach. We removed the pylorus because we believed that it was the source of a hormone which stimulated acid gastric secretion. One advantage of

leaving the pylorus intact is the ease with which the closure may be accomplished and duodenal fistulas obviated. In this group of resections we have had one duodenal fistula and this was efficiently dealt with by means of Potter's technique.

Gradually, over a period of 8 years our operation of gastric resection became more radical. This attitude was determined by the results seen in the follow up clinic. For 3 years we have done a radical subtotal gastrectomy, removing the pylorus and most of the lesser curvature of the stomach. We have reached this decision for the following reasons: recurring ulceration occurred in some cases with small gastric resections. The free hydrochloric acid in the stomach is not decreased as certainly by a small as by a large gastric resection. We have not encountered a single case of anemia which was not due to insufficient food or a badly balanced diet, the latter explained in many instances by economic stress. Such patients readily responded to a proper diet with iron therapy.

We have come to believe that there is no very great handicap arising from the small stomach. Such is compatible with comfort and efficiency despite the diet, work, and environment of a laborer. The primary mortality in our series is not forbidding. This operation is followed by the lowest incidence of jejunal ulceration which we have experienced after any operative procedure. Table III shows the relative incidence of the various

Fig 6 A graphic record of the balance between fluid intake, which includes that taken by all routes, and fluid output, which includes urinary output and fluid withdrawn through a duodenal tube. If the total fluid loss is greater than the intake, the volume of loss is recorded below the zero line, and if the fluid intake exceeds the loss, such volume of gain is recorded above the zero line. By means of this record it is easy to determine whether our method of procedure is maintaining an adequate fluid balance.

ous operative procedures together with the mortality. The late results of gastric resections for duodenal ulcer are tabulated in Table IV.

An analysis of the results of gastric resection reveals a low mortality. There were 3 deaths. One was believed to be due to pulmonary embolus on the tenth day. This was a clinical diagnosis, as no autopsy was permitted. The 2 other deaths were the result of an error in interpreting the gross pathological lesion. Both were interpreted as being malignant, and a very radical operation was carried out.

In the first case a diagnosis of pyloric carcinoma was made. The patient was an elderly male, admitted with coma and tetany from vomiting. After adequate pre-operative preparation, a gastric resection was carried out. He died of pneumonia, and had the correct diagnosis of duodenal ulcer been made, only a gastro-enterostomy would have been done. In the second case an erroneous diagnosis of carcinoma of the bile papilla was made and Whipple's resection of duodenum and pancreas, with transplantation of the common bile duct, was carried out. The patient died of peritonitis.

The mortality from a gastric resection for a recognized duodenal ulcer is very low. If we could exclude the 2 cases erroneously diag-

nosed in the gross as carcinoma from our series of 131 cases, we could present statistics of 129 resections for duodenal ulcer with 1 death from a pulmonary embolus, an accident which is apt to occur even with much more minor procedures. This would give an operative mortality of 0.77 per cent. When it is recalled that our operative procedure is carried out only on patients who are suffering from a serious lesion, which, having resisted all non-operative therapy, leaves the patient seriously disabled, then some risk is justifiable. That such a low operative mortality can be indefinitely maintained is too much to hope. That

†These 2 cases at present comfortable on medical regimen.

Fig 7 X-ray study of a short loop posterior gastroenterostomy taken in the erect position showing the stomach held up on the shelf of the gastrocolic omentum. Subsequent studies show the stoma to lie higher than the pyloric antrum with resulting imperfect drainage of the stomach and ultimate development of a jejunal ulcer.

it has been maintained over the period from the 1st of July, 1929, to date is due to a very careful selection of patients for operation, careful and adequate preparation, and perfect co-operation between the medical, surgical, and operating room staffs, combined with a careful and prolonged postoperative supervision of diet and work. The recurrences following the Schoemaker or Billroth I type of operation have evolved for us a definite principle. In one case the ulcer base in the pancreas was not removed, and in the second case a limited resection was done. We now believe that no type of resection accompanied by a gastroduodenal anastomosis should be carried out for a duodenal ulcer unless all the local pathological tissue, including the base of the ulcer, be excised. It thus becomes obvious that there will be practically no cases of duodenal ulcer which require operative therapy

Fig 8 Details of Finney pyloroplasty in which the stoma is large and extends below the entrance of the common bile duct.

in which this procedure is applicable. In one instance with excision of a jejunal ulcer following a gastroenterostomy, the stump of stomach following a limited resection was anastomosed to the side of the descending duodenum. An anastomotic ulcer occurred in 6 weeks, and a massive hemorrhage occurred in 8 weeks after operation. Re-operation confirmed the clinical diagnosis of anastomotic ulcer. We have not used this type of reconstruction since.

When a radical subtotal gastrectomy with removal of the pyloric antrum and most of the lesser curvature was the primary operative procedure, we have to date only one case with possible stomal ulcer. This diagnosis is based only on clinical and x-ray studies made in January, 1937. The patient is comfortable on diet, and was carrying on his responsibilities as a captain in charge of a large lake freighter, until lightning pains in his legs enforced a rest. A repetition of his gastric and x-ray studies in September, 1937, showed no evidence of any organic lesion in his gastrointestinal tract. Has his tabetic state any association with the possible stomal ulcer?

In view of the foregoing data, when a patient's disability warrants a gastric resection we have abandoned all procedures except a radical subtotal gastrectomy, with removal of most of the lesser curvature and the pyloric antrum. Thus we believe to be the correct surgical procedure for the young individual with a high free hydrochloric acid content in

Fig 9 The application of the three forceps before the division of the duodenum, and the method of closing the duodenum. The application of the Schoemaker clamp is also shown and the method of outlining the stoma near the greater curvature.

the stomach, no pyloric obstruction, no history of massive hemorrhage, and a penetrating duodenal ulcer unrelieved by a non-operative regimen. Ogilvie, in a recent conversation, stated that he has had a disturbing incidence of jejunal ulceration following his cases of gastric resection in which the pylorus was left *in situ*. He is at the moment modifying his operative procedure.

In short, for all gastric ulcers in which operation is indicated, a subtotal gastrectomy with excision of the ulcer, is carried out. If the ulcer has invaded the pancreas or liver, the ulcer base is left undisturbed. We use a posterior gastro-enterostomy or a Finney pyloroplasty for a scar stenosis at the pylorus—a Finney pyloroplasty in the middle aged or elderly patient with a penetrating ulcer who has never had a massive hemorrhage and who has a low free hydrochloric acid content in the

stomach. Where massive hemorrhage has occurred from a duodenal ulcer, a subtotal gastrectomy is carried out, with ligation of the blood supply to the duodenum. In the young individual with a duodenal ulcer and obstruction, no massive hematemesis, and high free hydrochloric acid in the gastric contents, if operation be indicated, then a radical subtotal gastrectomy is advised. In duodenal ulcer occulta, a radical subtotal gastrectomy is carried out, the ulcer being left *in situ*, as any attempt at removal would be futile and disastrous.

Where acute perforation of a duodenal ulcer has occurred, we believe that the surgeon's sole responsibility is to save life. We have previously shown that the simple procedure of tying a free or pedunculated fat graft over the perforation is sufficient to accomplish this. The results obtained are shown in Table V.

Fig 10 Scheme of dividing duodenum and separating the pyloric end of the stomach in the presence of a penetrating posterior duodenal ulcer preparatory to exteriorizing the ulcer

TABLE 1—ACUTE PERFORATED DUODENAL ULCERS

Total number of cases	60
Deaths (3.3%)	2
Dead pulmonary embolus on the tenth day	1
Dead cardiovascular accident on operating table	1

In a total of 60 consecutive cases operation has been done with 2 deaths. One death occurred on the tenth day from pulmonary embolus, and autopsy revealed healing at the site of perforation, and no peritonitis. The second death occurred in an elderly male while on the operating table before the ulcer was closed. He was the victim of serious cardiovascular disease, and we believe some cardiovascular accident occurred which was the cause of death. No autopsy was permitted. These results have settled for us beyond all argument the proper technical procedure to carry out for an acute perforation of a duodenal ulcer.

The immediate pre operative management

Fig 11 Method of closing duodenal stump and exteriorizing the base of penetrating posterior wall duodenal ulcer which has been left *in situ* and undisturbed

and preparation we believe to be of the utmost importance in safeguarding the patient during and immediately following the operation. We are firmly convinced no patient should be submitted to a major operation immediately following a prolonged bed rest and dietetic therapy. Such patients should be discharged from hospital, and be up and out of bed for at least 3 weeks before returning for operation. Such a management has definitely decreased the mortality and complications of our operations.

When pyloric obstruction from a duodenal ulcer is present, suction drainage of the stomach through an indwelling duodenal tube prolonged over 10 to 14 days, accomplishes a twofold purpose: first it permits restoration of tone in the overdistended stomach, second it is accompanied by the disappearance of the edema in the gastric wall. If operation be undertaken when the gastric wall is edematous, infection is more prone to occur along the suture line. We believe the infection in the edema about a gastric ulcer to be much more serious than such accompanying a duodenal ulcer. To free the gastric wall from edema is therefore most important in the prep-

This should be kept in a refrigerator until used

aration of the patient suffering a gastric ulcer. To accomplish this, x-ray examination should confirm the fact that the indwelling duodenal tube has entered the duodenum, in order that the stomach may be kept at rest. Feeding is carried out through the tube. Many mixtures may be used, but that shown in Table VI has proved efficient in our experience.

This mixture is given in doses of 1 to 3-ounce volume throughout the 24 hours, and in addition 3,000 cubic centimeters of 10 per cent commercial glucose in saline is allowed to drip into the stomach by means of an intravenous apparatus during the same period. This does not necessitate the patient being confined to bed, as the tube may be readily disconnected in order that the patient may take short walks about the hospital, and thus maintain general muscle tone. This regimen supplies 2,520 calories per 24 hours.

After 3 weeks the edema in the stomach wall about the ulcer is definitely lessened. This can be confirmed by x-ray studies showing increased motility of the gastric wall about the ulcer. The safety of the operation is therefore much greater. During this period of preparation it is necessary, in the patient suffering from pyloric obstruction from a duodenal ulcer, to supply fluid and nourishment by the intravenous administration of saline, glucose, and blood. Sufficient fluid must be administered to maintain a urinary output of 30 ounces or more in 24 hours. When the anemia is severe, and not responding to iron and die-

Fig 12. Production of artificial edema in gastrohepatic omentum high on the lesser curvature, with the method of isolating and triple clamping the left gastric artery.

tetic therapy, blood transfusion may be carried out. If the urgency for operation be great because of persistence of bleeding, the continuous drip transfusion advised by Marriott is admirable.

Mr. Gordon-Taylor (9) has stressed, however, that if massive drip transfusion be used as a pre-operative procedure on patients suffering from a severe hematemesis, it must be used immediately following the hemorrhage and operation undertaken as soon as a satisfactory hemoglobin level has been reached. We aim to raise the hemoglobin to 80 per cent before operation, and the transfusion is continued during and after the operation. His experience with this method of dealing with a severe hemorrhage accompanying a gastric or duodenal ulcer has been most happy. However, in instances in which he has deferred the drip transfusion until many days following the hemorrhage, when secondary anemia, with its associated disturbances, has become well established, the results have been disastrous, even though a high level of hemoglobin had been attained before operation. We have, however, on many occasions carried out extensive gastric operations on patients with a low hemoglobin. This is possible if a severe degree of anemia has persisted for some weeks, in order that the patient's metabolic processes may adjust themselves to a low level of hemoglobin. It then becomes possible to do exten-

Fig 13 Method of closing the newly formed lesser curvature. The frill remaining after removal of half the clamp is oversewn and buried with a second layer of continuous catgut and reinforced with interrupted silk. Preparation for a posterior Polya reconstruction by uniting the lateral cut margin of the posterior layer of the lesser sac by interrupted sutures to the posterior wall of the gastric remnant. The method of suturing the remnant of the gastrocolic omentum over the duodenal stump to make a more secure closure is also shown.

sive operations in the presence of an established and severe anemia which would be disastrous if undertaken soon after the development of even less severe anemia.

After a massive hematemesis when the actual gross bleeding has ceased we give food by mouth. The volume and caloric value of the food is rapidly increased until within 4 or 5 days the patient is taking the full ward diet containing an abundance of animal protein, the only refinement being that the vegetables are puréed and the meat and fowl put through a mincer. We have no instance in which we considered this procedure to initiate further hemorrhage. The value of this type of high caloric diet containing an abundance of animal protein, in the therapy of patients who have suffered a massive hemorrhage, we believe is beyond question. It increases the hemoglobin

in a manner which in our experience, was impossible with previous ulcer diets (Fig 4).

A further pre operative preparation which we believe to be of value is to accustom the patient to the presence of an indwelling duodenal tube. All patients who are being operated upon for gastric or duodenal ulcer are sent to the operating room with a duodenal tube in the stomach.

Because following partial gastrectomy, peristaltic contraction is abolished in the resected stomach, and because edema is present in a varying degree about the suture line there is in some instances a temporary delay in gastric emptying. A gross postoperative gastric retention may be present in the absence of vomiting. In order that there should not be an undue amount of gastric retention a careful chart is made of the fluid intake and

Fig 14 The use of the two stay sutures to prevent axial rotation of jejunum, also the insertion of pursestring sutures to hitch proximal jejunum well up on the lesser curvature, thus preventing gastric contents from emptying into proximal jejunal loop. Clamps are shown at the anastomosis for clarity, but we prefer to dispense with clamps, as they are too traumatic.

output in the stomach. Suction through the tube empties the stomach at frequent intervals. This prevents any undue strain on the suture line from overdistention of the resected stomach. Further, it prevents an increase of the edema in the stomach wall which is always associated with gastric retention. The fluid intake and output from the stomach is recorded on a graphic chart (Fig 5). The total fluid balance is also recorded and expressed graphically on a chart (Fig 6). This total fluid balance is determined by estimating the intake as the total fluids administered by mouth, rectum, interstitially, or intravenously. The fluid output is estimated as the fluid which has been withdrawn from the stomach in addition to the urinary output. This obviously neglects fluid loss by respiration and perspiration, but if sufficient fluid is administered to ensure a urinary output of

30 ounces or more in 24 hours, the patient is definitely protected against dehydration. If normal emptying of the stomach be unduly delayed over 5 or 6 days, we believe that edema about the suture line is an important contributing cause. Following the suggestion of Ravdin, we give such patients a transfusion of 500 cubic centimeters of citrated blood, for the sake of the serum protein which they receive. This procedure has, on occasions, given most spectacular results, even though with the methods available we had not been able to demonstrate a low serum protein.

The anesthesia we believe to be important. If the patient be elderly, or very markedly undernourished, a preliminary sedative of morphia and hyocine followed by an abdominal wall block with one-half per cent novocain, accompanied by splanchnic anesthesia after the method of Braun, is the procedure of

Fig 15 The completion of the retrocolic anastomosis the medial layer of gastroduodenal omentum being sutured to the anterior wall of the stomach. The duodenal stump is covered with fat and the diagram (inset 3) shows the proximal jejunal loop well sutured on the newly formed lesser curvature showing how the discharge of gastric contents must go into the distal jejunal loop.

choice. In the more robust individual, we represent the minority who favor spinal anesthesia. We use nupercaine. Our experience with this type of anesthesia, administered and supervised by an expert anesthetist has been most happy. The meticulous dissection and freedom from operative trauma possible with this procedure is of great advantage to primary healing, with a minimum of tissue reaction and wound pain.

We have for many years made a practice of giving a citrate blood transfusion of 500 cubic centimeters volume during the operation whenever a gastric resection has been performed. This has not been associated with any regrets. The satisfactory convalescence which our patients experience we believe to be due in part at least to this procedure.

While chest complications follow all types

of anesthesia, we believe that the absence of constricting abdominal dressings and the elimination of heavy retention sutures in the abdominal wall enabling the patient to breathe freely and with less pain is of real value. Expert nursing, which includes rolling the patient from side to side every 2 hours and stimulating overbreathing by having the patient frequently inhale carbon dioxide for the first 48 hours following operation, will decrease greatly the incidence and seriousness of the postoperative chest complications. A serious pneumonia is now an infrequent postoperative complication.

A detailed account of all the technical procedures is quite superfluous. There are, however, a few procedures which we have found of value in gastric operations. In the performance of a posterior gastro enterostomy, we are

impressed with the value of a long proximal jejunal loop. If a short or no-loop type of operation be done, particularly in a long-waisted, viscerotopic individual, the stoma in the erect posture is held up to a higher level than the greater curvature of the stomach. This results in an imperfect emptying of the pyloric antrum, and can readily be demonstrated by x-ray studies (Fig. 7). The important technical procedure in a satisfactory Finney pyloroplasty is a thorough mobilization of the descending duodenum. By incising the peritoneum lateral and parallel to the long axis of the second portion of the duodenum, this may be readily accomplished without trauma or blood loss. The stoma should be ample, and should reach a level distal to the entrance to the common bile duct or the ampulla of Vater (Fig. 8). Observance of these 2 points is essential to achieve the results of which this operation is capable. Since we have come to appreciate these details, and have learned how to mobilize the duodenum easily and safely, we are increasing the application of this operation.

In a subtotal gastrectomy, the lesser sac is opened below the greater curvature. This enables the identification and protection of the middle colic artery. As the division of the anterior layer of the lesser sac is carried toward the duodenum, the division by knife dissection of the reflection of the peritoneum onto the posterior wall of the pyloric antrum, together with the division of the peritoneum on the medial and lateral sides of the descending duodenum and duodenal cap, exposes adequately the duodenal blood supply and thoroughly mobilizes the first portion of the duodenum. This latter we believe is of the utmost importance in permitting an efficient closure of the duodenal stump and eliminating duodenal fistulas. The pyloric vessels and the duodenal branch of the pancreaticoduodenal artery are triple clamped and divided in such a manner as to leave two clamps on the stumps of the vessels. This permits of placing with ease and accuracy, on the proximal portion of the vessels, two ligatures, and does much to prevent accidental hemorrhage.

Shenstone's method of closing the duodenum is accomplished simply, by virtue of

Fig. 16 Details of the end-to-end gastroduodenal anastomosis as originally suggested by Schoemaker.

the free mobilization (Fig. 9). Three Kocher hemostats are placed across the duodenum just distal to the pyloric sphincter. Division of the duodenum is made, leaving 2 forceps on the stump. One of these is removed, and the frill of crushed duodenum oversewn. The second clamp is then removed, and with the same suture a second row of sutures is inserted which effectively imbeds the first row. If the first suture of this second layer is placed parallel to the long axis of the duodenum and then continued as an over and over stitch, it invaginates the corner very well, and the opposite corner is closed by ending the over and over stitch as a purse string. A third row of interrupted sutures of fine silk tied over the fatty remnant of the gastrocolic omentum completes a very satisfactory closure.

Occasionally a posterior wall duodenal ulcer is large and penetrating into the pancreas. Under such circumstances the duodenum is opened laterally just distal to the pyloric sphincter, and the stomach and duodenal cap trimmed away, thus leaving the ulcer base undisturbed (Figs. 10 & 11). The mucous membrane of the duodenum is closed by an over and over suture, and thus exteriorizes the ulcer base. A second layer of over and over serous to serous suture reinforces the closure.

With interrupted silk sutures approximating the peritoneum over the pancreas and the peritoneum of the lateral wall of the duodenum, the closed stump is forced into the ulcer base, and the whole area is thus reperitonealized. This not only assures ade-

quate closure of the duodenal stump, but also protects the general peritoneal cavity should any pancreatic secretion leak from the ulcer base, as such would readily find its way into the lumen of the duodenum. When the duodenum is adequately closed, the pyloric end of the stomach which had previously been wrapped in gauze and tied with hernia tape, is carried to the left. Sharp knife dissection and division of the peritoneal reflection of the lesser sac onto the fundus of the stomach will free the stomach to a remarkable degree. Injection of the gastrohepatic omentum above the lesser curvature just distal to the esophagus with 20 cubic centimeters of $\frac{1}{2}$ per cent novocain accomplishes two purposes (Fig. 12)—first, the straining and vomiting which occasionally accompany the necessary traction of the lesser curvature at this stage of the operation are eliminated. Second, the artificial edema produced permits the easy and bloodless isolation of the left gastric artery from the lesser curvature of the stomach. This artery is triple clamped and doubly ligated in a manner similar to that used in controlling the duodenal blood supply. The application of a Schoemaker clamp enables a safe and radical excision of the lesser curvature, the size of the gastric stoma at the greater curvature being determined by the application of crushing forceps with blades 2 inches long (Fig. 9).

The closure of the lesser curvature is accomplished by oversewing the frill remaining after removal of the outer half of the Schoemaker clamp and burying this line of suture by a second over and over continuous catgut suture. A third layer of interrupted fine silk sutures completes the closure of the newly formed lesser curvature (Fig. 13). The restoration of continuity of the gastro intestinal tract may be accomplished either by an anterior or a posterior Polya. If the former is employed, an enterocenterostomy should not be carried out. It is unnecessary and nullifies whatever virtue there may be in the intimate contact of the biliary, duodenal and pancreatic secretion with the gastric contents.

Axial rotation of the jejunum in gastro jejunal anastomoses is responsible for many of the mal functioning stomas. We have been amazed how easily and unwittingly such ro-

tation is accomplished, even when one is on guard against such an eventuality. We have found that an interrupted stitch placed between the stomach and jejunum at either end of the proposed stoma, and held so as to produce tension along the proposed suture line during the completion of the anastomosis will prevent such a technical error (Fig. 14). One or two pursestring sutures holding the proximal limb of the jejunum over the distal inch of the newly constructed lesser curvature accomplish 2 purposes: first, they secure against leakage at the angle formed between the reconstructed lesser curvature and the jejunum. Second, they prevent the stomach from discharging its contents into the proximal jejunal loop (Fig. 15). If the resection be carried out for a gastric instead of a duodenal ulcer, we choose, when conditions permit a restoration of gastro intestinal continuity by the Schoemaker technique. Instead of closing the duodenum, a single non crushing clamp controls the duodenal stump until the operation has proceeded to the completion of the closure of the new lesser curvature. Then an end to end anastomosis is carried out between the stoma at the greater curvature of the stomach and the duodenum (Fig. 16). The line of anastomosis is then encircled by the remnant of the fat containing gastrohepatic omentum.

This insures a safe and satisfactory union. A meticulous and accurate closure of the abdominal wall with the elimination of heavy retention sutures in the skin completes the operation. The dressing is simply a strip of gauze held over the wound with mastisol. This eliminates all constricting abdominal binders.

Water by mouth is allowed frequently, as soon as the patient is returned to bed not more than an ounce being given at one time. Other food is withheld until gastric emptying has been satisfactorily established. In 8 to 10 days after this period the diet has been increased until it becomes a non residue diet containing adequate animal protein, the vegetables being puréed and the meats put through a mincer. Careful supervision of the convalescence and the observance of a sound medical regimen for 6 months after operation are

essential Tobacco should be permanently dispensed with

SUMMARY AND CONCLUSIONS

1 In duodenal ulcer, surgical therapy becomes necessary only if the complications of perforation, penetration, stenosis, or recurrent hemorrhage are present.

2 Operation for benign gastric ulcer will rarely be necessary if Cleaver's method of medical regimen is instituted

3 Operation must secure relief of symptoms, restored efficiency, and the greatest possible security against recurrence of ulceration

4 A consideration of the site of the ulcer and the character of the gross pathological lesion, together with the accompanying biochemical and physiological disturbances, is essential in determining the optimum operative procedure for the individual patient

5. An operation must decrease the free hydrochloric acid content of the stomach, relieve gastric and duodenal spasm, establish efficient gastric emptying, include the excision of all gastric ulcers, and ligature of the blood supply of the duodenum in the cases in which a duodenal ulcer is accompanied by massive hemorrhage

6 The optimum operation for any patient is based upon the following data: the age of the patient; the results of fractional gastric analysis, the presence or absence of pyloric stenosis, if stenosis be present whether due to scar or edema, the site of the ulcer; and the degree of self-discipline which the patient has achieved

7 In a patient suffering a duodenal ulcer

with scar stenosis, we advise a posterior gastro-enterostomy or a Finney pyloroplasty. If there is no pyloric stenosis, in an elderly patient with a low free hydrochloric acid and no massive hematemesis, we do a Finney pyloroplasty. In all other indications for operation for duodenal ulcer we do a radical subtotal gastrectomy, with removal of the pyloric antrum.

8. A subtotal gastrectomy with excision of the ulcer is the procedure of choice when operation is required for a gastric ulcer.

9 In an acute perforation of a duodenal or gastric ulcer, simple closure as outlined is all that is necessary to save the patient's life.

10 Pre-operative and postoperative safeguards are enumerated.

11. Important technical details of the various operative procedures are outlined

LESIONS OF THE INTERVERTEBRAL DISC AND LIGAMENTA FLAVA

Clinical and Anatomical Studies

HOWARD C. NAFFZIGER, M.D., VERNE INMAN, M.D. and
JOHN B. de C. M. SAUNDERS, F.R.C.S. (Ed.), San Francisco, California

OVER a period of years much speculation has centered about the mechanism responsible for low back pain in that group of patients in whom a diagnosis has been made of disorders of the sacro iliac joint, the lumbosacral region, or both. Moreover, most of these patients have shown no x ray evidence of abnormality, and such cases have been fruitful sources of debate and argument as to the underlying cause of the disability. As might be expected when no well defined pathological changes are recognizable, the treatment has not been satisfactory. At various times attention has been directed primarily to the removal of focal infections and again to the correction of what were considered to be skeletal or postural strains with various functional disturbances.

While such symptoms may be produced by a variety of causes attention to two structures concerned in the production of these symptoms—the intervertebral discs and the ligamentum flavum—will demonstrate the source of a considerable number of them. Either an injury to the intervertebral discs or a thickening of the ligamentum flavum, or both, may be responsible. Displacements of portions of the intervertebral discs, particularly the central portion which herniates backward into the spinal canal, and injury to the ligamentum flavum with subsequent thickening and fibrosis, can be demonstrated pathologically.

The patients in whom these changes have been found are not ordinarily those with mild or transient pain. We have in fact, seen a number selected from many others because of the intractable character of their pain which had resisted varied forms of treatment. Most

of our patients were referred by orthopedic surgeons after prolonged efforts had been made to give relief. Strapping, postural exercises, massage and baking, plaster casts and jackets, traction, fasciotomy (Ober), and even lumbosacral and sacro iliac fusions had been tried. These are mentioned to indicate that the patients in the group which we are discussing have had severe and really intractable pain. It is our experience that when such a group of selected patients is studied, the incidence of displacement of a portion of an intervertebral disc or enlargement of the ligamentum flavum, or both, will be found to be very high.

We have again reviewed and investigated anatomical factors bearing on these lesions and the mechanisms involved. From the literature and from recent detailed dissections by Drs. Verne Inman and John Saunders of the University of California staff, certain important relationships have evolved.

Owing to the great interest which has been displayed in recent years with regard to lesions affecting the intervertebral disc, it is hardly necessary to give here more than a very brief outline of the structure of this important organ, an outline necessary as a preliminary to a discussion of the ligamenta flava, intervertebral canal, spinal nerves and injuries related to them.

The space between each two vertebral bodies is occupied by the intervertebral fibrocartilaginous disc. The intervertebral discs vary in vertical thickness in different parts of the vertebral column. They are thinnest from the third to the seventh thoracic vertebra and thickest in the lumbar region. In both lumbar and cervical regions each disc is thicker anteriorly than posteriorly, in this wise assisting in the production of the anterior convexities which characterize the vertebral column.

From the Departments of Surgery and Anatomy, University of California Medical School.
Presented before the Clinical Congress of the American College of Surgeons, Chicago, October 25-29, 1937.

in these regions. In the thoracic region, the reverse occurs in correspondence with its anterior concavity. Apart from variation in detail, the anatomy of each intervertebral disc is essentially the same.

Each individual disc consists essentially of three parts. First, a circumferential portion formed for the most part of oblique and spirally arranged fibers passing from one vertebra to the other, but exhibiting regionally great variations, no doubt associated with variation in function. In section this portion is arranged in a series of concentric lamellæ and has received the name annulus lamellosus or fibrosus. The annulus is firmly attached into the substance of the adjacent bone by means of the so called fibers of Sharpey and may be regarded, for practical purposes, as equivalent to the capsule of the joint. It is supported anteriorly by the anterior longitudinal ligament and posteriorly by the posterior longitudinal ligament. The anterior longitudinal ligament is a wide, well defined structure exhibiting, characteristically, expansions at the level of the discs. On the other hand, the posterior longitudinal ligament is a poor, ill defined structure supporting the disc only in the middle line and often displaying deficiencies where it is related to the disc. It is important to note that posterolaterally on either side where the disc comes into relationship with the intervertebral foramen, it is unsupported by any extrinsic ligamentous structure. In these regions the disc frequently bulges backward to occupy a considerable portion of the lower half of this foramen.

Second, a soft, pulpy, elastic portion approximately occupying the center of the disc and constituting what is known as the nucleus pulposus. This pulpy center is of peculiar functional significance. It has arisen in part from the primitive axis about which the embryo has developed—the notochord. In the healthy disc it possesses a considerable inherent turgor and elasticity and because of these properties it serves to distribute pressure over the vertebral body. It can be most nearly described as an elastic ball-bearing, changing in shape and position under functional demands, and so distributing and absorbing the mechanical shocks to which the spine is con-

tinually subjected. In the lumbar region the nucleus pulposus is placed a little dorsal to the center of the disc, and in flexion it tends to move in a still more dorsal direction.

Third, the fibrocartilaginous disc is bounded above and below by cartilaginous plates which cover the bearing surfaces of the contiguous centers. These cartilage plates, though regarded by some as analogous to the articular cartilages of other bones, really constitute an integral part of the disc, bounding it above and below so that it possesses a drum-like form. This conception we owe to Schmorl.

We know of no adequate detailed anatomical description of the ligamenta flava. They consist predominantly of yellow elastic tissue and join adjacent laminae and articular processes. Whereas the ligamentum flavum is a continuous structure, it is convenient both for descriptive and clinical reasons to subdivide it into two portions. The medial half, the broader and thicker part of the ligament, is attached to the contiguous laminae and may with advantage be called the interlaminar portion. The thinner lateral half is less wide and tapers off as it extends laterally. It is attached predominantly to the articular processes and is related to the interarticular joint and capsule. This part will be referred to as the capsular portion. This division into interlaminar and capsular portions is suggested by some difference in direction of the fibers of the two parts. The fibers of the interlaminar part are vertical in position, whereas those of the capsular portion run obliquely downward and laterally (Fig. 2).

The interlaminar portion is attached inferiorly to the upper border of the lamina below. This attachment is indicated on the bony specimen by a well defined groove (Fig. 1, inset), the anterior margin of which variously exhibits sharp, thin plaques or spicules of bone which extend up into the anterior face of the corresponding ligament. These spicules are variable in size, number, and position and may perhaps be regarded as ossification in the ligamentum flavum, but we have noted that they are attached to the lamina and are more in the nature of an ossific extension from the bony attachment. Calcareous matter has been observed in the ligamentum flavum removed at

Fig. 1 Frontal view of the articulated lumbar spine. The vertebral bodies have been removed at their junction with the pedicles thus permitting examination of the dorsal wall of the bony vertebral canal.

operation, and, in our opinion this is in part nothing but ossific matter derived from these spicules which must necessarily be fractured from their attachments when the ligament is surgically removed.

Superiorly the interlaminar portion is attached to a well defined irregular and rough area, occupying the lower half of the lamina (Fig. 1). This area is separated from the smooth upper half of the lamina by a sharp ridge. The ridge characteristically exhibits a small bony spicule at the junction of the attachments of the interlaminar and capsular portions, but the bony plaques found below have not been observed at the upper attachment. Owing to this arrangement, the inferior half of each lamina is excluded anteriorly from

the neural canal and the upper smooth half of the lamina alone is directly related to the spinal dura. The medial end of the interlaminar portion blends with its fellow of the opposite side in the midline at the base of the spinous process. Laterally, each interlaminar portion is continuous with, and almost inseparable from the capsular moiety, except for the difference in direction of the fibers of the two parts. The interlaminar portion is for the most part a direct posterior relation of the spinal dura.

The capsular portion is attached below to a groove (Fig. 1) which extends along the periphery of the inferior articular process to a point a little beyond the intervertebral foramen. Above the ligament is attached to the

Fig 2 Dissection of the right posterolateral wall of the vertebral canal in the lumbar region. The attachments and extent of the ligamenta flava are clearly shown.

inferior border of the pedicle and lies just below the groove for the spinal nerve (Fig. 2) which is found on the inferior aspect of this structure. Laterally the ligament, considerably attenuated, blends with the capsule of the interarticular joint, some little distance lateral to the intervertebral foramen. This portion of the ligament excludes the joint from the neural canal and from the lower half of the intervertebral foramen.

The intervertebral foramina of the lumbar region are of special clinical significance and will receive major consideration here. The bony foramen or the foramen as visualized by x-rays, is approximately the shape of an inverted pear. This description scarcely holds for the fifth lumbar foramen which is more oblique and irregular, as is likewise, though to a lesser extent, the fourth. In x-ray examinations it is observed that the shape of the foramen changes with alteration in position, being larger and more elongate in flexion. Its upper boundary, formed by the pedicle and, more anteriorly, by the lower part of the vertebral body of the upper of the two contiguous vertebrae, is deeply notched (inferior vertebral notch). The spinal nerve, closely applied

Fig 3 Dissection of the third and fourth lumbar intervertebral foramina, viewed from within the vertebral canal. The apposition of the intervertebral disc and ligamentum flavum obliterates the inferior half of the bony foramen. The spinal nerve leaves through the upper half of the bony foramen. Note the relationship of the outlined nerve to the sulcus between the ligamentum flavum and the disc at the foramen above that of its exit.

to the medial surface of the pedicle, grooves this structure, forming the sulcus nervus spinalis (Fig 2). This sulcus, in the case of the upper lumbar foramina, extends onto the inferior aspect of the pedicle at the apex of the inferior vertebral notch. At the fifth lumbar foramen and to a lesser extent at the fourth, the sulcus extends obliquely forward for some distance outside of the foramen, grooving the root of the pedicle, base of the transverse process, and adjacent body. In consequence, the fifth lumbar nerve, which has a very oblique anterior and downward inclination, is almost completely overhung by bone and lies close in to the lateral side of the body. It is important to recognize that the spinal nerves of the lumbar region occupy only the uppermost portions of their respective intervertebral foramina, closely applied to the

Fig 1 Frontal view of the articulated lumbar spine. The vertebral bodies have been removed at their junction with the pedicles thus permitting examination of the dorsal wall of the bony vertebral canal.

operation, and, in our opinion this is in part nothing but ossific matter derived from these spicules which must necessarily be fractured from their attachments when the ligament is surgically removed.

Superiorly the interlaminae portion is attached to a well defined, irregular and rough area occupying the lower half of the lamina (Fig 1). This area is separated from the smooth upper half of the lamina by a sharp ridge. The ridge characteristically exhibits a small bony spicule at the junction of the attachments of the interlaminae and capsular portions, but the bony plaques found below have not been observed at the upper attachment. Owing to this arrangement, the inferior half of each lamina is excluded anteriorly from

the neural canal and the upper smooth half of the lamina alone is directly related to the spinal dura. The medial end of the interlaminae portion blends with its fellow of the opposite side in the midline at the base of the spinous process. Laterally, each interlaminae portion is continuous with and almost inseparable from the capsular moiety except for the difference in direction of the fibers of the two parts. The interlaminae portion is for the most part a direct posterior relation of the spinal dura.

The capsular portion is attached below to a groove (Fig 1) which extends along the periphery of the inferior articular process to a point a little beyond the intervertebral foramen. Above the ligament is attached to the

usual, or be about to emerge from the sac, or may have just emerged, enclosed within its own sheath. It should be recognized that the nerve, no matter what relation it bears to the dural sac, is lying at this point in the sulcus between the intervertebral disc and the ligamentum flavum on the medial aspect of the lower half of the intervertebral foramen above that which gives it egress. Furthermore, the nerve is relatively fixed in this region because of its proximity to its point of emergence, although lying within the spinal dura. It has also been observed that the spinal theca in this region is normally slightly indented (Fig. 4) by the disc anteriorly and the ligament posteriorly with the nerve occupying the interval. These intimate relationships are of the greatest importance, for in this position the nerve is peculiarly vulnerable to encroachments by either the ligamentum flavum or the intervertebral disc, or both.

Protrusions from the posterolateral portion of the intervertebral disc may encroach upon the intervertebral foramen or protrude posteriorly and involve the nerve passing to the foramen below, in the latter case deforming the spinal theca at the level of the intervertebral disc above the foramen of the nerve involved.

We have had the unique opportunity of examining, postmortem, an instance of enlargement of the ligamentum flavum and observing its precise relationships. This example was found in the course of dissection on cadaver material and in consequence no history is available. The lesion occurred at the level of the lumbosacral junction on the left side. The ligamentum flavum was considerably enlarged, rough, irregular, and nodular. It protruded forward, impinging on the first sacral nerve. The nerve was found almost buried in the sulcus between the enlarged ligament and the corresponding disc.

The relative violent forces which act upon the spinal column are perhaps not sufficiently well appreciated. The column itself, freed of muscles, maintains a state of equilibrium to which it tends to return when a deforming force is applied. This equilibrium is established by two forces necessarily equal, but acting in opposite directions. One of these forces is

expansive and tends to separate the vertebral bodies. It depends upon the turgor of the intervertebral discs. This force has been experimentally ascertained in the cadaver, by Petter, to approximate 30 pounds in the individual discs of the lumbar region. The other force is tensile and resists separation of the vertebral bodies. It depends upon the various ligaments such as the annulus lamellous, the anterior and posterior longitudinal, the interspinous, the supraspinous, and intertransverse ligaments. The elastic nature of these forces permits of spinal movements. When these forces are liberated by separation of the neural arches from the bodies, the expansile force residing in the nucleus pulposus elongates the anterior part of the column while the tensile force of the various ligaments of the neural arches shortens the posterior portion. The change approximates 10 per cent of the total length of the column. These intrinsic forces, together with the primary and secondary curves, give to the column its extraordinary resiliency.

Under functional stress, the pressure exerted upon and distributed through the lumbar vertebræ and intervertebral discs must be enormous. They must, of course, carry the superincumbent body weight. Furthermore, in lifting a weight, the lumbar region carries the brunt of the pressure attendant upon use of the spinal column as a lever of the third class. We have estimated by analysis of the force vectors, resultant upon the lower lumbar discs in lifting a weight of 50 pounds, that this pressure amounts, under average conditions, to about 500 pounds. Under other conditions, there are fleeting periods during motion in which the pressure is considerably in excess of this rough estimate. In addition, when the spine is flexed, the nucleus pulposus in the lumbar region migrates dorsally, tension is thrown upon the posterior portion of the annulus and, if some rotation should accompany flexion, the annulus is further subject to torsional stresses. The magnitude of these forces, the dorsal migration of the nucleus, the stresses thrown upon the posterior part of the annulus, no doubt account for the greater frequency of dorsal herniations in the lower lumbar region. These are sufficient to account

Fig 4 A dissection exposing the vertebral canal and its contents in the lumbosacral region by removal of the vertebral bodies. The lateral relations of the spinal theca and the course of the spinal nerves through the intervertebral foramina are shown

inferior aspect of the pedicle, and bear no direct relationship to the lower half of the foramen. The relationship of nerve to interarticular joint is very slight, occurring only at the most lateral part of the joint. At this point the nerve is no longer within the foramen proper, but at its wide and funnel like exit.

The lower half of the foramen is bounded below by the shallower superior vertebral notch on the upper aspect of the pedicle below. This portion of the foramen is narrow (Fig 3) and bounded anteriorly by the backward protrusion of the intervertebral disc and

posteriorly by the forward bulging of the ligamentum flavum, due to partial offsetting of the inferior articular process. With the soft tissues intact, this portion of the foramen is little more than a slit. In some instances these structures are in actual contact.

On the medial side of the lower half of the intervertebral foramen the apposition of the backward bulging intervertebral disc and the forward protrusion of the ligamentum flavum create a definite sulcus (Fig 3). This sulcus is related to the spinal nerve. Due to individual variations, the nerve may be lying at this point, within the dural sac, as is more

usual, or be about to emerge from the sac, or may have just emerged, enclosed within its own sheath. It should be recognized that the nerve, no matter what relation it bears to the dural sac, is lying at this point in the sulcus between the intervertebral disc and the ligamentum flavum on the medial aspect of the lower half of the intervertebral foramen above that which gives it egress. Furthermore, the nerve is relatively fixed in this region because of its proximity to its point of emergence, although lying within the spinal dura. It has also been observed that the spinal theca in this region is normally slightly indented (Fig. 4) by the disc anteriorly and the ligament posteriorly with the nerve occupying the interval. These intimate relationships are of the greatest importance, for in this position the nerve is peculiarly vulnerable to encroachments by either the ligamentum flavum or the intervertebral disc, or both.

Protrusions from the posterolateral portion of the intervertebral disc may encroach upon the intervertebral foramen or protrude posteriorly and involve the nerve passing to the foramen below, in the latter case deforming the spinal theca at the level of the intervertebral disc above the foramen of the nerve involved.

We have had the unique opportunity of examining, postmortem, an instance of enlargement of the ligamentum flavum and observing its precise relationships. This example was found in the course of dissection on cadaver material and in consequence no history is available. The lesion occurred at the level of the lumbosacral junction on the left side. The ligamentum flavum was considerably enlarged, rough, irregular, and nodular. It protruded forward, impinging on the first sacral nerve. The nerve was found almost buried in the sulcus between the enlarged ligament and the corresponding disc.

The relative violent forces which act upon the spinal column are perhaps not sufficiently well appreciated. The column itself, freed of muscles, maintains a state of equilibrium to which it tends to return when a deforming force is applied. This equilibrium is established by two forces necessarily equal, but acting in opposite directions. One of these forces is

expansive and tends to separate the vertebral bodies. It depends upon the turgor of the intervertebral discs. This force has been experimentally ascertained in the cadaver, by Petter, to approximate 30 pounds in the individual discs of the lumbar region. The other force is tensile and resists separation of the vertebral bodies. It depends upon the various ligaments such as the annulus lamellous, the anterior and posterior longitudinal, the interspinous, the supraspinous, and intertransverse ligaments. The elastic nature of these forces permits of spinal movements. When these forces are liberated by separation of the neural arches from the bodies, the expansile force residing in the nucleus pulposus elongates the anterior part of the column while the tensile force of the various ligaments of the neural arches shortens the posterior portion. The change approximates 10 per cent of the total length of the column. These intrinsic forces, together with the primary and secondary curves, give to the column its extraordinary resiliency.

Under functional stress, the pressure exerted upon and distributed through the lumbar vertebræ and intervertebral discs must be enormous. They must, of course, carry the superincumbent body weight. Furthermore, in lifting a weight, the lumbar region carries the brunt of the pressure attendant upon use of the spinal column as a lever of the third class. We have estimated by analysis of the force vectors, resultant upon the lower lumbar discs in lifting a weight of 50 pounds, that this pressure amounts, under average conditions, to about 500 pounds. Under other conditions, there are fleeting periods during motion in which the pressure is considerably in excess of this rough estimate. In addition, when the spine is flexed, the nucleus pulposus in the lumbar region migrates dorsally, tension is thrown upon the posterior portion of the annulus and, if some rotation should accompany flexion, the annulus is further subject to torsional stresses. The magnitude of these forces, the dorsal migration of the nucleus, the stresses thrown upon the posterior part of the annulus, no doubt account for the greater frequency of dorsal herniations in the lower lumbar region. These are sufficient to account

for herniation, in a normal disc, from a single trauma. In others, repeated trauma of the discs with attendant weakening of the annulus, or in those with such degenerate changes as we have often observed, these forces alone would serve as an adequate cause of herniation. It should be further noted that, in reaching forward to one side, the anatomical arrangement in the lumbar region is such as to limit that rotation which so freely occurs in the thoracic segments. This limitation forces lateral bending in the lumbar region, which puts the major stress on the posterolateral portion of the annulus and ligamentum flavum of the contralateral side. Such a mechanism would readily account for the unilaterality of lesions to one or both of these structures occurring in the neighborhood of the intervertebral foramen and involving, in the case of the ligamentum flavum, its capsular portion.

It is many years since Virchow demonstrated that, in flexion of the spine the lumbar region contributes very little to the movement except in that the curve is obliterated and the segment becomes straight. This limitation of movement is in contrast to that which occurs in extension. Phylogenetic history in the adoption of the orthograde position, evidences the enormous development of the sacrospinalis muscles necessary for the maintenance of the erect posture. These muscles have their *point d'appui* on the lower thoracic cage and thoracic spine. They play over, rather than on the lumbar segments. The lumbar spine may be regarded, in consequence, as a single lever. It is apparent that, should the lumbar spine develop an anterior concavity, the tendency would be for the sacrospinalis muscle to approach the axis of the lumbar spine. Such an approach would place the muscle in a position of mechanical disadvantage for protection of the spine, or for recovery from the hyperflexed position. The difficulty of lifting a heavy weight with the fully flexed spine is a familiar observation. Likewise when the spine is forced into hyperflexion its integrity is no longer fully guarded by the musculature and strain is thrown upon the dorsal ligaments and ligamentum flavum, notably the interlaminae portion. Such a mechanism sufficiently explains injuries to the ligamentum flavum. The

association of lateral bending with forward flexion in producing unilateral lesions has already been discussed.

It has been pointed out that structurally the ligamentum flavum consists predominantly of elastic tissue and is normally under tension. When torn or injured it fibers, retracts. Healing occurs by scar formation. That such scars should undergo hypertrophy is not surprising. Numerous examples of such hypertrophies can be observed in other situations. They characteristically occur in such regions where movement is unavoidable and free, such as on certain parts of the abdominal wall and in the neck. The persistent stimulation of healing wounds results in excess of fibrous connective tissue, and hypertrophy is greatest where movement is most. Gregg pointed out that such hypertrophied scars are not true keloids but a local response to stimulation and that they are merely hypertrophied cicatrices. Once injury and scar formation occur in the ligamentum flavum, there can be no question that the factor of movement is continually operative, resulting in hypertrophy of the cicatrix. These conclusions are confirmed by the appearances of every example of hypertrophy of the ligamentum. We have been able to examine histologically

Though displacements of cartilage and fibrocartilage from the intervertebral discs may occur at any level of the spine, the majority will be found in the low lumbar region, most often between the fourth and fifth lumbar vertebrae though sometimes between the fifth lumbar vertebra and the sacrum, or between the third and fourth lumbar vertebrae. The production of symptoms by enlargement of the ligamentum flavum has in our experience been limited to the same low lumbar region, for although these structures are present higher up they are much thinner and are not subject to the same gross alterations.

Over a period of years, cartilaginous masses have been removed from the spinal canal by various surgeons after a diagnosis of tumor of the spinal cord had been made. Less often, but in a considerable number of instances, alterations in the ligamenta flava have been found and have been noted in the literature. The nature of the cartilaginous masses and the

source have only recently been thoroughly understood. Frequently they have been considered to be new growths—that is chondromas. The recent interest in them has been due largely to their intensive study by Drs Mixer, Barr, and Hampton, and their associates at the Massachusetts General Hospital.

The herniations from the intervertebral discs vary in position and frequently the extruded mass is not visible at once, even after laminectomy has been performed. With proper localization of the lesion before operation, extensive laminectomy is not needed, but usually the laminae that are removed are completely rongeué away, including the laminal portions of the articular facets. In special instances, with particularly well localized extrusions, unilateral laminectomy may be adequate, but, in most instances, complete removal of the fourth and fifth laminae is necessary to permit thorough exploration of the canal and to follow the course of the roots. After removal of these laminae the ligamenta flava will be seen as yellow bands crossing the dura. When their condition is pathological, they will be found not only greatly increased in thickness, but will show evident fibrosis with no clean line of cleavage between them and the dura, and will need to be dissected free. In such instances a transverse groove and indentation will be left in the dural canal. Under this, the dura is frequently very greatly thickened. Having resected the ligamentum flavum, both sides of the dural canal are carefully palpated, particularly along the area of the emergence of the spinal roots. A small nodule may be felt in relation to them, not infrequently, however, it will be difficult of detection. If so, the dura is opened, the filaments of the cauda equina are freed from their arachnoidal covering, and the interior of the dural canal is inspected. From its inner surface each root is observed and, only then, may a nodular protrusion be evident. Frequently it is of very small size—not more than from three-quarters of a centimeter to one centimeter in diameter—but will be seen compressing a nerve root as it emerges from the dural canal, and ordinarily the root so involved will be injected and edematous. The dura covering these protrusions will show an alteration

in appearance, small telangiectases being apparent.

When these masses are found extradurally, they are usually removable by the same route. At times the fibrocartilage will be lying free and only need be lifted out with forceps. At other times, it will have a fibrous covering which, when incised, will permit the white stringy material to be withdrawn, leaving a clean, smooth, shiny cavity from which a grooved director or probe will often pass directly down into the space between the intervertebral discs. At times the fibrocartilage may be extruded to considerable distances, and we have had the experience of finding a major part of it immediately beneath the laminae after their removal, compressing the dura from its dorsal aspect. This material had extruded from in front of the dura, passed around its side, and had come to lie beneath the laminae. Such an extreme protrusion is unusual. In the instances in which the mass is recognized only after the dura is opened, we have removed it through this transdural approach. A short incision over the mass will usually permit the material to be picked out readily, and the incision may be closed by a single silk suture. The incision in the posterior surface of the dura, through which the work has been done, is then completely closed (Figs. 5, 6, 7, 8).

When thickening and alteration of the ligamentum flavum are found, the ligament is completely dissected out, not only on the dorsal surface of the dura, but as it passes forward deep to the articular facets, and is cut close to its attachments to the intervertebral foramina. In most of our series of patients, the symptoms resulted from rupture of the intervertebral disc, a minority had gross and microscopic alterations in the ligamenta flava, and, in one, both conditions were present. From the anatomical studies it is apparent that the two conditions might well be associated and that a combination of alteration in the position of a portion of the intervertebral disc and a thickening of the ligamentum flavum, would enormously encroach upon the nerve in its groove.

With reference to the history given by these patients, their ages varied from 18 to 63

Fig 5 Transdural exposure of a displaced fibrocartilage

years, but most of them were in the active working period of life. A history of trauma caused by falls, bending, lifting, or torsion of the spine was given by the majority of patients, though in some cases, no history of trauma could be elicited. In still others, there was chronic repeated trauma, as in one woman who had done a great deal of horseback riding and jumping. In patients with rupture of the ligamentum flavum, trauma was consistently present and often the patient had felt a sudden snap in the back.

Fig 7 The appearance of a fibrocartilage after removal.

Fig 6 Transdural exposure of a herniated fibrocartilage compressing a root.

Most of the patients complained of both low back pain and sciatica, although the latter complaint was the more prominent. Relatively few had low back pain alone. As previously noted, these patients had had all manner of treatments with varying degrees of benefit but, in general, no lasting relief. It seems to us of particular interest that the symptoms may subside at times so that one frequently obtains a history of recurrent attacks, with periods of entire relief between them extending over a number of years.

With reference to the dislocation of a portion of an intervertebral disc, it must be appreciated that the clinical picture may vary greatly, depending on the amount and the location of the protruded material. We have seen sufficient extrusion of fibrocartilage to compress the entire content of the dural canal causing complete paralysis below the level of the lesion, loss of motor power in the sacral distribution, sensory loss and incompetence of the sphincters. Such a marked compression of the entire dural canal is unusual, and more often there is pressure on a single root. Sciatic pain is the most frequent and troublesome complaint. It may be aggravated by straining, coughing and sneezing, although this is not consistent. Usually the radiation of the sciatic pain is indicated as being down the outer side of the leg, extending into the foot on

Fig 8 The cartilage extrudes backward and in the midline b Transdural exposure c Incision of the ventral dura to expose the mass

its dorsal surface Listing of the spine is common and may be marked In writings on the subject it has been stated that the list is commonly toward the side of the lesion, but very frequently we have found listing to the opposite side (Fig 9) An absent or altered Achilles reflex on the affected side is perhaps the most common objective finding The motor and sensory findings depend on the location and the structures compressed Ill defined sensory alterations over the outer side of the calf and the area supplied by the external

popliteal nerve are rather common, though sensory loss is not pronounced The muscles supplied by the external popliteal nerve may be weaker than those on the opposite side and, at times, there is a discrepancy in the degree of involvement of the tibialis anticus as compared to the extensor hallucis or the common extensors of the toes Atrophy in the peroneal muscles is seen in long standing cases, but the normal fullness over the belly of the tibialis anticus is rather commonly noted Movements of the back are limited and painful and

Fig. 9. Girl 18 years of age. List is away from the lesion.

the patients assume a variety of positions in sitting and lying in order to obtain comfort. Straight leg raising gives severe pain.

In the presence of such a history and the findings herein noted, particularly when there are objective evidences of involvement of a nerve root, compression by the dislocation of cartilage or the enlargement of the ligamentum flavum must be strongly considered. We have not ventured, however, to make a positive clinical diagnosis, or to operate without the aid of x-ray confirmation. In the final decision as to whether or not laminectomy is indicated, we lean heavily on the roentgenologist. His familiarity with the condition and his interpretation of the x-ray studies are of the greatest importance. Plain x-ray films are not diagnostic, although in certain instances there is some narrowing of the intervertebral disc on the affected side. Ordinarily, spinal puncture with the introduction of lipiodol is required. The puncture is usually done at as low a level as possible—usually between the fourth and fifth lumbar spinous processes. Occasionally, as the needle penetrates the dura and distorts it as it is pushed ahead, the patient will experience intense pain which follows the radiation of the root involved. It is exceptional for the dural canal to be so greatly encroached on or for the lesion to occur at a sufficiently high level to show any block-

age by the Queckenstedt test. We have, however, been able to reproduce the pain of which the patient habitually complains, by compression of the veins of the neck and increase in spinal pressure. In a considerable proportion of instances, the spinal fluid will show an increased total protein although the absence of such an increase does not speak particularly against lesions of the discs or the ligaments.

Lipiodol must be introduced in adequate amount—4 or 5 cubic centimeters. Following this, the patient is placed upon a tilting x-ray table in the face down or prone position and under the fluoroscope, the movement of the lipiodol in the canal is followed as, with the tilting of the patient, it is made to flow up and down the canal. If there is an irregular protrusion into the canal, the column of lipiodol will be found to bend around it, or to hesitate in passing it and often, by inclining the patient slightly to one side or the other, such an alteration may be exaggerated. Such findings are rechecked and final films are taken with the lipiodol about the point of obstruction. A lack of symmetry in the column of lipiodol, a constant notching at a level which corresponds to the root involved or the distortion of a root at its point of emergence from the dural canal, is considered diagnostic. In cases of doubt, the x-ray examination should be repeated at the end of 10 days or so. It is not uncommon for a second examination to give clearer diagnostic evidence. An hour glass constriction of the dural sac and the enclosed column of lipiodol has been seen in enlargements of the ligamentum flavum. Notching of the lipiodol column is more characteristic both of the protruded cartilage and the thickened ligament.

The results of laminectomy with the removal of the displaced cartilage or enlarged ligament, in relieving pain in the back, sciatica, and such neurological findings as may have been associated with them, have been excellent and attended with little risk. Certain questions are usually asked as to the effect on the back of the laminectomy itself and the use of lipiodol. Laminectomy in the low lumbar spine entails no disability for those not engaged in heavy physical work, though

some limitation in bending is present for a period of weeks. In relation to those who are engaged in doing heavy manual labor, the question is not so easy to answer. Some of our patients have returned to such work; others have been unable to perform the heavier parts of their duties, so that, in certain of the patients engaged in manual labor, laminectomy has been followed at the same stage by a bone graft

As to the use of lipiodol, this procedure is reserved for patients in whom the probability is strong that such pathological changes as we have described will be found. It has certain disadvantages and is not to be used indiscriminately. The most common complaint is of some discomfort referable to the sacral region and often a burning pain about the coccyx. When a condition is found warranting

operation, the lipiodol is entirely removed at that time. When the x-ray evidence has not been sufficient to justify operation, the lipiodol may cause discomfort for a considerable period of time.

The differential diagnosis between extrusion from the intervertebral disc and thickening of the ligamentum flavum is not easy to make, but the same surgical approach is required in both.

The patients discussed were among those who had been diagnosed as having some lumbosacral or sacro-iliac disorder which did not yield to such treatments as strapping, exercises, physical therapy, traction, and lumbosacral and sacro-iliac fusions. If temporary relief was secured, the episodes recurred. In such selected patients, lesions of the disc or of the ligamenta flava are frequent.

THE RELATION OF CHRONIC CYSTIC MASTITIS TO CARCINOMA OF THE BREAST

DEAN LEWIS, M D , F A C S , and C F GFSCHICKTER, Baltimore, Maryland

IT is just a little over one hundred years ago that the first attempts were made to differentiate between benign and malignant tumors of the breast. In Lecture XIII, which appears in *The Principles and Practice of Surgery* written by Sir Astley Cooper and published in 1835, appears the following

The diseases of this organ have been too much considered as being of a malignant nature, and the females who have had the misfortune to have tumours in their bosoms have often been unnecessarily submitted to an operation under the idea of the complaint being cancerous. I shall therefore proceed to state what I have been able to learn from various diseases of the organ, to discriminate the malignant from the more benign complaints and to point to cases which really require removal in distinction from those in which the operation is entirely unnecessary.

Cooper gives the following account of pathological changes in a group of benign mammary conditions

A change in the nature of the swelling occurs as it enlarges. At first it is uniformly solid but afterwards distinctly divided into a solid and fluid part the latter fluctuating so as to inform the surgeon of the existence of fluid. If this part be punctured a liquid having the character of serum is discharged but the swelling soon becomes distended again and continues to grow. At length the tumour acquires enormous magnitude and some of the largest swellings in this organ are of the hydatid kind. I have twice seen swellings not of this description rather larger than the hydatid but generally the largest of the breast are of this kind. From Mrs King at Charing Cross I removed one which weighed thirteen pounds but frequently they are removed when still small under a supposition that they are scirrhous tubercles.

It is a complaint I have seen at all ages after twenty but more frequently in advanced age than in youth.

There may be some doubt as to whether many cases described by Cooper were cystic

From the Surgical Department of the Johns Hopkins Medical School and Hospital

Presented before the Clinical Congress of the American College of Surgeons, Chicago, October 23-29, 1937

mastitis. Undoubtedly he recognized the disease, for he described over the fluid part of the cyst a slightly blue appearance. Thus, as far as we can determine, is the first mention of this feature, the significance of which Bloodgood has emphasized so much during the past years.

Brodie was apparently the first to recognize that the cysts originated in the milk ducts, and to attach some etiological significance to the absence of lactation. Lecture XXIV was published in 1846. It was devoted to cystic disease of the breast. The following appears in the published lecture

The disease of which I propose to treat on the present occasion is an affection of the female breast. It is one of general interest in various ways and among others in this that in its advanced stages it is liable to be confounded with carcinoma although it is not really of a malignant nature. I should not have been able to trace its exact history if I had trusted altogether to my hospital experience. I have not met with any description of it in text books corresponding to what I have observed of its actual progress. You will presently see how this is easily explained by the disease assuming a wholly new character as it proceeds so that if you were to look at two cases of it one in the early and the other in the more advanced stage without having witnessed the intermediate changes which have taken place you would scarcely be able to recognize their identity. Let me not, however, be misunderstood as to representing that no notice whatever has been taken of it by surgical writers.

The account which Sir Astley Cooper has given of the hydatid breast has been taken principally from cases of this disease and there have been allusions to it in the treatise on *Diseases of the Breast* lately published by Velpeau.

Brodie's contribution to cystic mastitis was the recognition of the age incidence and its frequent occurrence in women who had not lactated.

The observations made by Reclus deserve comment. They are as follows

The first characteristic is the extreme abundance of the cysts. Without doubt one would be able to

count by the naked-eye at least fifty, but microscopic examination shows innumerable cysts, not only in the tumor itself, but disseminated throughout the entire gland. The second characteristic is that in this specific disease one finds cysts in the acini and in the milk ducts, and in all the lobes and lobules. The third characteristic is the involvement of both breasts. The occurrence of tumors in both breasts is uncommon, but we have found in the cases which we have studied cysts in both breasts. It is perhaps because both breasts are affected that the lesion has been unrecognized as cystic in character. The disease very often is characterized only by irregularities on palpation, associated at times with but little pain. To the ordinary clinician the lesion might be regarded as a constitutional physiologic phenomenon.

This statement seems almost prophetic in light of the isolation of the ovarian hormones and the reproduction in animals by their use of the histological picture of cystic mastitis. Burrows, as will be shown later, has even suggested that the lesion be called estrogenic mastopathy.

Schimmelbusch gives the following description of the disease bearing his name:

Cyst adenoma mammae (*Maladie kystique*) is a disease which is not uncommon in middle aged women. It occurs with equal frequency in those who have and have not borne children. Numerous cysts the size of a pea or bean, rarely larger, develop. These are filled with greenish-brown, somewhat sticky fluid, and are found especially in the posterior part of the gland. The diseased breast is not adherent to the neighboring structures. The disease affects almost without exception both breasts at the same time, or one shortly after the other. Microscopically there is found a marked increase in the number of acini. The epithelium may undergo slight hyperplasia or form a cast of the alveolus. Two or more acini may fuse, and as a result of the poor nourishment of the epithelium cysts may form, the contents of which are a combination of secretion and degeneration. The connective tissue shows no evidences of inflammatory or proliferative changes. It is known, however, that a carcinoma may develop upon this disease, for among 43 cases, a carcinoma of the breast was found three times.

Nature Numerous names have been given to diseases of the breast characterized by cyst formation. These are all based upon histological peculiarities. There is no need to recall all, such as senile parenchymatous hypertrophy, cystiphorous desquamative epithelial hyperplasia, and fibro-adenomatosis cystica mammae. The terms are based largely upon the anatomical findings, and suggest no etio-

logical relationship to glands of internal secretion, although there has been abundant evidence to show that a distinct relationship exists between ovarian function and the breast. The mechanism by which the activities of the ovaries, uterus, and mammary glands are regulated, co-ordinated, and synchronized is fairly well understood at the present time. The idea which formerly prevailed, that the changes which occurred in the breast during pregnancy were due to nervous influences, has been shown to be wrong. Clinically changes are frequently observed in the breast during the menstrual cycle; most frequently before menstruation begins. The woman complains of a sense of fullness of the breast and some tenderness. Upon palpation a granular, flattened mass, which disappears when menstruation begins, may be felt. Definite changes in the breast during the menstrual cycle have been described. Differences of opinion there may be as to the interpretation of these changes, but all agree that changes do occur which are correlated with the different phases of the menstrual cycle. The isolation of the different ovarian hormones has made it possible to study the changes produced in the breast when the hormones are introduced into the circulation.

The conclusions arrived at by Burrows in an article recently published entitled "The Pathological Changes Induced in the Mammæ by Oestrogenic Compounds" are as follows:

- 1 The earliest pathological effect of estrin observed in the mammæ of male mice is a proliferation of the mammary ducts, that is to say, gynecomastia. This proliferation of ducts is occasionally accompanied, especially when the treatment has been prolonged, by the formation of what look like clusters of acini.

- 2 Speedily following the proliferation of ducts is their dilatation with the formation of mammary cysts.

- 3 The next stage is that of hyperplasia of the epithelium lining the ducts; sometimes accompanied by an increase of the periductal stroma. This stage of hyperplasia, combined with the presence of cysts, represents the chronic cystic mastitis of the old and the "cystic mastopathy" of the new terminology. In view of its causation, it might perhaps better be termed "estrogenic mastopathy." In advanced cases epithelial anaplasia may be seen in the ducts. All the foregoing changes are produced by estrin, in the same sequence in both male and female mice.

Fig. 1 A whole mount of the breast of a castrate female rat showing the production of cystic disease. This rat received 100 gamma of estrin for twenty days beginning with the twenty first day of life. The specimen was taken 5 days after the last injection.

Recent studies by Astwood, Geschickter, and Rausch have shown that during the first 6 weeks of life the mammary gland develops independently of the ovary or testis, and that the gland enlarges with equal rapidity, whether the gonads are present or not. The breast of the normal female possesses no lobules or acini except during pregnancy but shows periodic secretory changes recurrent with the estrous cycles. The manner in which estrin modifies mammary development is dependent upon the dosage, the age of the ani-

Fig. 2 Whole section from the breast of a case of adenosis. The lobular development is reduced in amount. There is increased fibrosis and the terminal tubules at base of gland show irregular hyperplastic epithelial changes.

mal, and the state of nutrition. During the first 2 weeks of life, estrin causes no demonstrable changes. After the age of 3 weeks, estrin in small or moderate doses accelerates the extension of the duct tree. Large doses cause a stunted type of growth, with irregular widened ducts, distorted tubules or end bud proliferation. Continued high doses cause secretory changes which are initiated with cyst formation. The gland becomes prematurely aged, the hyalinized connective tissue is increased in amount, and marked changes in the ducts are noted.

The changes which have just been described are not unlike those seen in Schimmelbusch's disease. As has been stated, large cysts are not usually found in this disease, but a widespread transformation of the parenchyma into small cysts, associated with epithelial overgrowth, occurs.

Classification. Notwithstanding the amount of work that has been done upon cystic mastitis, there is still a lack of uniformity of opinion as to how some phases of the process should be classified.

A number of different names, such as papilloma intracanalicular, duct cancers, cystadenoma papillare, carcinoma villosa and cyst epithelioma intracanalicular have been given to the papillomatous growths which are encountered in the medium sized and large ducts. Many different views have been expressed

Fig. 3 High power photomicrograph of the epithelial changes in the case shown in Figure 2. Normal lobule formation is being replaced by non-encapsulated adenomatous changes in the region of the terminal tubules.

Fig 4 Gross specimen showing characteristic tissue removed from a case of multiple blue dome cysts. The smooth walled cyst is surrounded by dense fibrous tissue

concerning the relation that these may bear to cystic disease of the breast.

Koenig believed these to be true tumors which differed from and were not related to the epithelial proliferations noted in cystic mastitis. Tietze, on the other hand, thinks that the papillomatous growths observed in cystadenoma mammae are a part of the change and of the same nature, and ascribed to them a rôle in the development of cancer in cystic mastitis. Semb believes that the occurrence of multiple papillomas in cystic mastitis, their frequency and the histogenic analogy with the development of the disease render it necessary to regard the two processes as being closely related to each other, and concludes that the cystadenopapillomas must be conceived of as being formations belonging to the picture of cystic fibro-adenomatosis, or a part of that condition and connected especially with the later stages of that disease.

Certain papillomas appear as independent tumors. Many emphasize the relationship between these and carcinoma. Such papillomas are usually large, solitary growths and are not associated with the mammary changes seen in cystic disease. It will be seen from the above that there is no uniformity of opinion as to the nature of the small multiple papillomatous

Fig 5. Chart showing the relative frequency and the age incidence of adenosis and cystic disease

growths. Multiple papillomas do not seem to occur as a true tumor, but develop as the result of epithelial changes in cystic disease, and should be regarded as a part of the diseased process. Whether or not they are precancerous, or are liable to undergo malignant changes, will be discussed later, when the clinical histories of cases of cystic disease followed by us are discussed.

As one's experience with cystic mastitis increases, many lesions that were formerly regarded as malignant are placed in the benign group. The following indicates how Bloodgood changed his opinion over a period of a few years. Cases will be cited from the Johns Hopkins Clinic which will indicate how a change in the classification of lesions of this type has occurred as the specimens and the results have been restudied and correlated.

As an example, Bloodgood in 1904, basing his opinion upon microscopic examination alone, concluded that malignant epithelial change occurred in 10 per cent of all cystic disease. In 1906, he wrote that adenocarcinoma was already present in 50 per cent of the patients with adenocystic disease that he had examined. In 1921, he reported his experience with 350 cases of cystic disease in 128 of which the treatment had been local excision only. A follow-up showed that carcinoma had developed in 3 of these cases—an incidence of 2.3 per cent.

Fig 6 Photomicrograph of a small tumor removed from the breast of a patient of Dr Halsted's in 1897. The lesion was diagnosed microscopically as adenocarcinoma and the complete operation was performed. There were no metastases to the lymph nodes and the patient remained well for a period of more than 16 years. This lesion on restudy has been reclassified as benign.

Fig 7 Photomicrograph of a non-encapsulated adenoma, diagnosed adenocarcinoma from the biopsy performed in 1913. The complete operation was performed. The lymph nodes show no metastases and the patient was reported well 8 years later. This lesion also on restudy has been reclassified as benign.

Difficulties of making a diagnosis, both microscopic and clinical, are encountered in certain types of cystic mastitis. A study of some cases which have been observed in the Johns Hopkins Surgical Clinic will illustrate the difficulties and account for the change in opinion which has been made from time to time. Clinically intermittent retraction of the nipple has been observed. The following clinical note appears in the paper by Bloodgood upon "The Pathology of Chronic Cystic Mastitis of the Female Breast." The patient, examined by him in 1912 presented a variation in the clinical picture which he had observed once since, that is intermittent retraction of the nipple as a symptom of onset with induration of the breast chiefly in the nipple and areolar zone.

The patient a white unmarried woman aged 38 had intermittent retraction of the left nipple for 4 years and permanent retraction for 4 months while she had observed intermittent retraction of the right nipple for 4 months. On inspection both nipples seemed retracted on palpation the left nipple remained retracted while the right nipple bulged. There was an indefinite induration beneath both nipples. He performed the complete operation on the

left breast and then 3 weeks later, removed the right breast and then 6 months later removed the glands in the right axilla. The operation on the right breast was an illogical one but at my first pathologic examination I interpreted this case as an adenocarcinoma in chronic cystic mastitis. The patient was well 9 years later.

On pathological examination a non-encapsulated cystic adenoma was found beneath both nipples. The small, solid adenoma infiltrated the fat.

The following is the history of another patient who had an intermittent retraction of the nipple of 18 months' duration. When examined in 1912 the nipple was permanently retracted.

The patient was a widow aged 49 years. She had observed that the nipple of the left breast retracted and protruded on and off for 18 months. There had been no discharge from the nipple. She sought advice because of pain of 4 months' duration. On palpation nothing very definite was made out. The breast was explored and it was thought that there was a carcinoma just beneath the nipple. A radical operation was performed. In the laboratory a zone of non-encapsulated adenoma was found just beneath the nipple. The surrounding breast tissue was fatty and senile. The diagnosis was small, irregular stellate adenoma with some cystic adenoma. No metastases were found in the lymph nodes.

The patient returned 2 years later with a similar clinical picture in the right breast—intermittent retraction of the nipple of 1 year's duration, permanent retraction for the last 3 months. On palpation indefinite lumps were discovered in the breast. Because the diagnosis of adenocarcinoma in chronic cystic mastitis was still unchanged, a complete operation for cancer was performed. The gross and microscopic pathology of this breast was practically identical with that of the breast removed at the first operation.

Here are recorded 2 cases of chronic cystic mastitis with intermittent retraction of the nipple, and in each both breasts were finally involved.

Nine of 18 specimens (50 per cent) of non-encapsulated cystic adenoma in the cases studied by Bloodgood were removed at the Johns Hopkins Surgical Clinic. Only 1 of these showed microscopically fully developed cancer. All, with the exception of one, were at once or later subjected to the complete operation. During the same period, about 30 years, 9 specimens were sent to Bloodgood for diagnosis. These 9 specimens were sent by surgeons in 9 different states. This indicates that the lesion is rare, excites interest, and that pathologists disagree as to benignity and malignancy. A radical operation was performed immediately or later upon these patients. No metastases were found in the nodes. All have been followed. There have been no recurrences in this group and none has died of cancer. Bloodgood concludes, after studying this group of cases:

I am confident that it is this group of cases that has given rise to the impression that it is not dangerous to excise a malignant tumor of the breast, submit it to microscopic study, and then perform the complete operation for cancer some days or weeks later. This type of tumor, when diagnosed adenocarcinoma, increases the percentage of cures of cancer, not only in this group but the total percentage of operative cures of cancer of the breast. When these cases and some of those in group B B 13-8 were included in our cases of cancer of the breast they increased the percentage of five-year cures. When all cancers of the breast without metastases to the nodes and these two groups with the comedo-adenoma were included the percentage of five-year cures was more than 80. When these three groups were excluded the percentage of cures dropped to 60.

Bloodgood closes his article upon "The Pathology of Chronic Cystic Mastitis of the

Female Breast—Where Pathologists Disagree" with the following:

I have submitted sections of every type of chronic cystic mastitis, lactation mastitis, tuberculous mastitis, encapsulated cystic adenoma, fibro-adenoma, and intracystic papillomas to more than forty consulting pathologists, and I have their written diagnoses. In the majority of these there was some disagreement; the percentage of those favoring benignity varied from twenty to ninety.

In all of these demonstrations the sections illustrated in Figures 87 and 89 were included. On these 2 cases of fully developed cancer there was not a single disagreement.

During the same period many sections and tissues have been sent to me from other surgeons and pathologists with their diagnoses. I have never received one which proved to be a fully developed cancer that had not been diagnosed cancer. But I have received many with a diagnosis of cancer which, in my opinion, belonged to one of the above mentioned benign groups.

It is very interesting to record here again that in breast lesions, when good pathologists disagree as to malignancy, the patient lives; when there is agreement, there is always a large percentage of deaths from cancer.

EFFECT OF PREGNANCY AND LACTATION

Experimental work which has been cited indicates that there is a definite relationship between the ovarian hormones and cystic mastitis. It will be interesting to record the effects of pregnancy and lactation upon the breast when a diagnosis of cystic mastitis has been made. Sterility is not uncommon when this lesion exists, and we have had an opportunity to follow but a few cases. The history of four will be given.

McC. The patient, a white female aged 32 years, had had two children, the youngest being 10 years of age. In April, 1934, one ovary and two-thirds of the opposite ovary were removed because of cysts and the patient was told that no further pregnancies were probable. Following the operation, pain more pronounced in the premenstrum was noted in both breasts. The patient was first seen in November, 1935. At this time nothing abnormal was palpated in either breast but the pain had become continuous and there was mild galactorrhea. Cancer was feared. The patient was given reassurance that her condition was not cancerous and told to return in 6 weeks. When the patient returned in 1936 pain in both breasts had become constant. The menstrual periods had become irregular and the cycle was shortened to 21 or 26 days. At this examination indurated masses were found in the outer upper quadrants of both breasts. Definite masses were present in both breasts.

about 1 centimeter in diameter. One in the upper half of the left breast and one in the outer upper quadrant of the right breast. The breasts were shotty and had a definite edge. No hormones were given but the patient was told to return for treatment. She did not come back however for over a year.

The patient was next seen April 3, 1937. She was now 4 months pregnant. The pains in the breasts were now intermittent but sharper and more stabbing since pregnancy. On examination a definite edge could still be felt in the left breast and the nodule persisted in the left breast but not in the right. In the right breast an indefinite dense mass was palpated in the outer upper quadrant. There were no lumps and no definite edge. No treatment was prescribed. The patient was told to return in 3 weeks.

The patient was seen April 23, 1937. She is now 5 months pregnant. Pain has disappeared, the breasts are enlarged, and no masses can be felt in either breast. She was followed until after delivery when both breasts were normal to palpation.

D. H. The patient is a white female, aged 29 years, who is married but childless. She has had trouble with her right breast over 4 years. In 1925 she first noticed tenderness and a small mass about 2 centimeters in diameter in the lower inner quadrant. Recently a small tumor appeared to the outer side of last mentioned tumor. Both were small, smooth and cystic to palpation, when examined in January 1929.

In June 1929 the patient became pregnant. Both breasts increased rapidly in size at the end of the first month and from then on the tumors could no longer be palpated and no tenderness was noted. Following the birth of her first child in March 1930 the breasts have remained negative. She had a second child in August 1932 and when last heard from in October 1936 she had remained well.

E. K. The patient is a white female, aged 27 years, who is married but has no children. Her menstrual periods are regular. About 4 years ago severe pain was noted in both breasts before her periods. At first this soreness lasted for 1 week before periods. It is now nearly continuous. Four months ago a lump appeared in the right breast. The patient received sixteen injections of anterior pituitary like hormone and small doses of estrin (250 international units per c.c.) elsewhere. The tumor regressed under treatment but the pain was not affected and the patient was advised to have her breast off.

When seen in January 1936 the right breast was larger than the left but the breasts were otherwise normal to inspection. The left breast has a definite edge on palpation and is diffusely shotty or lumpy, particularly in the outer and upper quadrant. The right breast also has a definite edge but has a large flat dense area about 4 centimeters in diameter in the outer and upper quadrant. The region where the former lump was felt, the inner lower quadrant, is now negative.

The patient received 40,000 international units of estrin in January, 1936. Thereafter she received 10,000 international units once a month. The breasts

have remained free from tumors and free from pain since the second month of injections. She was seen in January 1937, and both breasts were negative at that time. In June 1937, there was some return of premenstrual pain. This was followed by rapid enlargement of both breasts and an Aschheim-Zondek test revealed that the patient was pregnant. She was seen August 20, 1937, when she was 3½ months pregnant. At this time both breasts were uniformly enlarged, tense, and free from nodules and pain or tenderness. In the last third of pregnancy the breasts softened and were negative to palpation.

Mrs. L. A. W. The patient is a white female, aged 33 years, married but childless. Her menstrual periods are regular. She has had trouble with her breasts for at least 10 years. In 1925 an operation was performed for the removal of a tumor from the right breast. In 1929 a tumor was removed from the left breast. In November 1932 tumors were removed from both breasts through incisions along the lateral borders of the breast. The lumps and fear of carcinoma have been the most pronounced feature of the case. The patient has recently gained weight. She has always been nervous and has a constant fear of cancer.

Examination shows two relatively small and misshapen lumpy breasts. Scars and tumors are found in both breasts. The largest lump is in the outer lower quadrant of the right breast and above this there is dimpling due to the former incision. There is no discharge from either nipple. At least eight small cysts can be palpated in the right breast, the majority in the middle of the upper half. There are four cysts in same location of left breast and two in lower outer quadrant. Multiple small cyst like tumors can be palpated at periphery of both breasts.

The patient received estrin therapy in November 1935—35,000 international units. The symptoms were somewhat improved in February, 1936. Patient has been free from pain but the cyst still remained in October 1936. In May 1937 the patient became pregnant and she has become less conscious of the lumps in her breast. These have not bothered her since the second month. The patient was asked to return for examination during pregnancy but because of the illness of her mother she did not do so. In November 1937 her breasts were examined by her obstetrician who sent the following report.

The patient is now 7 months pregnant. The right breast is negative except for a small nodule about 2 centimeters in diameter just above the nipple. The left breast is also negative except for a small mass 1 centimeter in diameter in the upper inner quadrant. Both nodules are not tender and are not attached to the skin or surrounding tissue.

CRITERION FOR ESTABLISHING RELATIONSHIP TO MALIGNANCY

Those studying the relation of malignancy and chronic cystic mastitis may be divided

into two groups. One group considers cystic mastitis a benign lesion with no etiological relationship to carcinoma, the other, a benign lesion but precancerous in nature. The group which regards the lesion as benign without malignant potentialities base their opinions upon clinical examinations and a careful, prolonged follow-up of patients operated upon and observed clinically over a long period. There are certain borderline cases, the nature of which has not been recognized. Not infrequently these have been regarded as malignant. The clinical behavior of such cases, however, has not justified the conclusions based upon histologic examination.

Campbell has followed a large number of cases clinically and he concludes:

One may approach the problem with the easy philosophy that total removal of the breast will for all time relieve the patient of worry and risk, the surgeon of responsibility. However, it is assumed that preservation of the breast, both from a functional and a cosmetic standpoint, is desirable and commendable if it can be accomplished with reasonable safety to the patient.

From the standpoint of risk of malignant change, there is no more justification for amputation of the breasts than for the routine removal of normal breasts to prevent the inevitable occurrence of cancer in approximately 2 per cent of the cases.

We have records of 1,048 cases of chronic cystic mastitis, of which 375 were cases of early adenosis — Schimmelbusch's disease. Two hundred seventy of the 375 patients were not operated upon; 105 were. Seventy excisions were performed and 35 radical removals, 9 of which were bilateral. Among the cases in which operation was not done or in which simple excision was performed, 76 have been followed 10 or more years. But two of these patients are known to have died of carcinoma originating in the breast. Eighteen died of other diseases during the period of follow-up.

In a second group are 158 cases of advanced adenosis. No operation was performed upon 57; a simple excision upon 57; radical removal of the breast upon 44; and in 9 of these both breasts were removed. Of these 158 cases, 97

TABLE 1.—ULTIMATE RESULTS IN 1,048 CASES OF CHRONIC CYSTIC MASTITIS

Adenosis	Cases	Cystic Disease	Cases
No operation	327	No operation	54
Early (operation)*	105	Simple cysts (operation)	386
Advanced (operation)	101	Multiple cyst (operation)	75
	533		515
Followed more than 5 yrs	271	Followed more than 5 yrs.	252
Died of breast cancer	3	Died of breast cancer	1

*With few exceptions the operations performed in these cases were simple excisions.

have been followed for a period of more than 5 years. But one of these is known to have died of a cancer originating in the breast—an incidence of about 1 per cent.

In the series are 515 cases of cystic disease. In 54 of these an operation was not performed. Simple excision was performed 395 times and radical removal of the breast 66. Two hundred and fifty of these have been followed more than 5 years, and of these but one has died of carcinoma of the breast originating in the breast — an incidence of 0.4 per cent (Table I).

Tissue from 2,675 carcinomas of the breast has been examined. In but 29 did the surrounding tissue show any well developed areas of adenosis; in 3 cystic disease was found. Less than 0.5 per cent of the changes found in Schimmelbusch's disease are found in the ordinary type of carcinoma of the breast, but approximately 30 per cent of comedo or duct carcinoma show histologically a relationship to adenosis (Schimmelbusch's disease).

These figures would seem to indicate that cystic disease and adenosis are not precancerous lesions, and that radical operations should not be performed as frequently as they are. Another form of therapy should be tried. Reclus' statement seems to be almost prophetic: "For we may finally conclude that the disease is really dependent upon some constitutional physiologic phenomenon." It seems that in chronic cystic mastitis the epithelial changes have been carried almost to the point of lactation, which is not reached. If lactation had occurred these changes would have disappeared during involution of the breast.

IMMEDIATE OR DELAYED TREATMENT OF ACUTE CHOLECYSTITIS

Liver Shock and Death

HENRY W. CAVE MD, FACS, New York New York

IT REQUIRES sound judgment to choose the opportune moment for surgical intervention in acute cholecystitis. Any attempt to standardize the time of operation in all cases is hazardous. In acute inflammatory disease of the gall bladder, as in acute hyperthyroidism, care in judging the individual case is of the utmost importance, if operative mortality and postoperative complications are to be kept at a minimum.

In the past 10 years considerable controversy has arisen as to the ideal time to operate, the recent literature on this subject has frequently been vague as to the definition of immediate or emergency operations and by no means explicit as to what is meant by an early operation. The purpose of this paper is to help clear up some of the confusion that exists, in order that we may more clearly interpret these terms. Certain beneficial pre-operative measures will be emphasized, and a postoperative complication termed "liver shock and death" will be discussed.

The idea must be clarified that immediate or emergency operations are synonymous terms. An early operation implies an interval of from 24 hours to 7 days, while delayed or late procedures indicate that the acute process has been allowed to subside, and the gall bladder is removed some weeks or even months later.

The recent trend toward earlier interference in acute cholecystitis has had a stimulating effect upon the leading surgeons of our country and abroad. Their opinions have been quite firm, but show a surprising lack of unanimity. At first glance one feels that their arguments are equally convincing, but on second thought, hesitates to take a definite stand without analyzing the situation more carefully.

The "immediate" group. A J. Walton, a noted English surgeon, as early as 1913 emphatically advocated immediate interference. He decried the fact that surgeons universally have agreed that acute appendicitis should be treated at once yet are reluctant to operate as emergencies on those patients who are suffering from acute cholecystitis. He emphasized that if the operation is carried out in the early stages, severe complications such as gangrene with perforation may be entirely prevented. He also points out the fact that the maneuver is facilitated by the edematous state of the tissues, and that if the operation is performed at a later stage the technical difficulties are increased.

Leriche and Cotte in 1918 advocated immediate cholecystectomy, and it is surmised from the article reviewed that the present tendencies in France are for intervention without delay.

Graham urges prompt operation. In a group of 198 consecutive cases, 20 patients were operated upon within 48 hours of the onset of the acute symptoms, with a mortality rate of 5 per cent, the remaining patients who were operated upon after the 48 hour interval suffered a mortality of 62 per cent. The single death in his first group was due to pancreatitis. Although his contention may be valid, it does not seem that there are sufficient numbers in the immediate group to warrant definite conclusions. He enumerates various reasons for immediate operation, the most important of which are:

1. No deaths followed early operations when acute cholecystitis was the only disease present at the time of the operation.

2. The necessary operations were simple ones.

3. Postoperative complications were few. He observes further that operations from 1

From the Surgical Service, The Roosevelt Hospital.
Presented before the Clinical Congress of the American College of Surgeons, Chicago, October 25-29, 1937.

to 34 days after admission to the hospital showed that:

1. Mortality was increased and in many the deaths were attributable directly to the delay.

2. Longer and more difficult operations were necessary.

3. The number of postoperative complications was greatly increased

Stone and Owings in a concise and enthusiastic manner approach the problem other than statistically. They suggest that, if it is a sound principle to remove immediately an inflamed appendix, or to suture immediately a perforated peptic ulcer, it is logical to treat acute lesions of the gall bladder in the same manner. They admit certain anatomical differences between the gall bladder and the source of more extensive and gross soiling than a leak in a distended gall bladder. They state that "anyone who realized the amount of infectious material that a diseased gall bladder may contain will not be inclined to underestimate the possibilities of contamination that its rupture may entail."

My own contention is that the acutely inflamed gall bladder but rarely perforates into the free abdominal cavity causing a diffuse peritonitis. The majority of perforations of this viscus occur so gradually that protective adhesions between the gall bladder, omentum, and colon are formed, and usually result in a localized abscess.

Stone and Owings are unconvinced of the argument that operations in the acute stage require greater skill and judgment than operations on the subsiding gall bladder. They think it is unworthy to compromise a principle of treatment on account of the lack of skill in the profession.

Finney, a reliable and conservative surgeon, believes in immediate operation. Heuer, in a most painstaking statistical and rationalized presentation, should be placed in this group of immediate operators. He gives a series of 153 cases, 65 per cent of which were subjected to operation the day of admission, 35 per cent being observed 48 hours or more before operation was performed. He feels that 20 per cent of all cases of acute cholecystitis are complicated by gangrene and perforation. He confesses that he does not operate

upon every case as an emergency; for operations have been deferred where pre-operative treatment seemed advisable.

The "early" group. From a careful study of the literature, I am impressed with the fact that the majority of surgeons can be classed in this group of so-called "early operators," who do not advise operation at once.

A valuable statistical contribution in favor of "early operation" (48 hours to 7 days) is that of Branch and Zollinger. In their study of 235 histories of patients admitted to the Peter Bent Brigham Hospital in Boston, they found 34 or 14.4 per cent were operated upon immediately for reasons of definite signs of peritonitis or of an impending perforation, with a mortality of 20.3 per cent; the remaining 195 patients were treated conservatively for an average of 4.7 days before operation, with a mortality of 8.7 per cent.

Many of the authors writing upon this subject have referred to Judd and Phillips as strong advocates of immediate intervention. When their article is carefully studied it is of interest to note that only 14 times in a series of 508 cases was an operation performed as an emergency measure. It is also of interest to note that in 68 of these cases the wall of the gall bladder was gangrenous; and in 61 of these 68 cases, it had perforated, with the formation of an abscess on 38 occasions. This shows that in over one-half of the cases in which the gall bladder was perforated, the lesion had walled off into a localized abscess, and only in three had the gall bladder ruptured into the general peritoneal cavity with an ensuing diffuse peritonitis. It seems to me that these statistics show that perforations of this viscus into the general abdominal cavity are relatively infrequent, as compared to that many cases (508) of acute appendicitis.

Once again the term "early" has been confused. Many of the investigators interested in this particular disease have classified Judd and Phillips as "immediate" operators, when in reality they must be placed in the "early" group.

The operative mortality in the group studied by Graham of Toronto, showed that in the group of patients operated upon immediately there was 16 per cent mortality, while

IMMEDIATE OR DELAYED TREATMENT OF ACUTE CHOLECYSTITIS

Liver Shock and Death

HENRY W. CAVE M.D., F.A.C.S., New York New York

IT REQUIRES sound judgment to choose the opportune moment for surgical intervention in acute cholecystitis. Any attempt to standardize the time of operation in all cases is hazardous. In acute inflammatory disease of the gall bladder, as in acute hyperthyroidism, care in judging the individual case is of the utmost importance, if operative mortality and postoperative complications are to be kept at a minimum.

In the past 10 years considerable controversy has arisen as to the ideal time to operate, the recent literature on this subject has frequently been vague as to the definition of immediate or emergency operations and by no means explicit as to what is meant by an early operation. The purpose of this paper is to help clear up some of the confusion that exists, in order that we may more clearly interpret these terms. Certain beneficial pre-operative measures will be emphasized, and a postoperative complication termed "liver shock and death" will be discussed.

The idea must be clarified that immediate or emergency operations are synonymous terms. An early operation implies an interval of from 24 hours to 7 days, while delayed or late procedures indicate that the acute process has been allowed to subside, and the gall bladder is removed some weeks or even months later.

The recent trend toward earlier interference in acute cholecystitis has had a stimulating effect upon the leading surgeons of our country and abroad. Their opinions have been quite firm, but show a surprising lack of unanimity. At first glance one feels that their arguments are equally convincing, but on second thought, hesitates to take a definite stand without analyzing the situation more carefully.

The "immediate" group A. J. Walton, a noted English surgeon, as early as 1923 emphatically advocated immediate interference. He denied the fact that surgeons universally have agreed that acute appendicitis should be treated at once yet are reluctant to operate as emergencies on those patients who are suffering from acute cholecystitis. He emphasized that if the operation is carried out in the early stages, severe complications such as gangrene with perforation may be entirely prevented. He also points out the fact that the maneuver is facilitated by the edematous state of the tissues, and that if the operation is performed at a later stage the technical difficulties are increased.

Leriche and Cotte in 1928 advocated immediate cholecystectomy, and it is surmised from the article reviewed that the present tendencies in France are for intervention without delay.

Graham urges prompt operation. In a group of 198 consecutive cases, 20 patients were operated upon within 48 hours of the onset of the acute symptoms, with a mortality rate of 5 per cent, the remaining patients who were operated upon after the 48 hour interval suffered a mortality of 62 per cent. The single death in his first group was due to pancreatitis. Although his contention may be valid, it does not seem that there are sufficient numbers in the immediate group to warrant definite conclusions. He enumerates various reasons for immediate operation, the most important of which are:

1. No deaths followed early operations when acute cholecystitis was the only disease present at the time of the operation.

2. The necessary operations were simple ones.

3. Postoperative complications were few. He observes further that operations from 1

writers. He quotes Heller as postponing the operation until the interval. There are other German surgeons, among them Enderlen and Hotz who 14 years ago found that the mortality following operations performed during the acute attack was double the mortality following procedures carried out during the remission.

Unquestionably a certain number of patients will not submit to immediate or early operation and in consequence endanger their lives by the sequelæ which follow gangrene and perforation.

Liver shock and death. Heyd in 1924 described an unusual complication following surgery on the gall bladder and biliary tract. There were certain unexplained fatalities which focused his attention upon the possibility that these deaths might be due to some form of liver disturbance. Thus the term came into use "liver shock and death." He divided these fatalities into three types.

1. The patients suffering from chronic cholecystitis with jaundice. Following operation they fail to regain consciousness and, with a rapidly rising temperature and markedly increased pulse rate, die within 36 hours.

2. Those suffering from obstructive jaundice. Following choledochostomy with drainage they progress satisfactorily for several days, then without any known exciting cause become delirious, and gradually lapse into coma. The escaping bile becomes less in amount and watery in color and consistency.

3. A rare condition. The patients with a diseased pancreas and bile ducts, without jaundice. After choledochostomy with drainage they appear to be progressing satisfactorily when suddenly there is a marked acceleration of the pulse rate, a fall in blood pressure, a suppression of urine, and a condition exhibiting signs of collapse; but occurring much later than is usually seen in shock which ordinarily follows cholecystectomy.

In 1926 the essayist (4) reported 3 patients who died within 40 hours after operation with immediate hyperpyrexia. One had a temperature of 107.2 degrees, another 106 degrees, and still another 107 degrees. Hemorrhage, peritonitis, pneumonia, and embolism were ruled out clinically. These were cases of chronic cholecystitis with cholelithiasis, and a chole-

cystectomy had been performed. None was jaundiced. The operations were performed without difficulty, in fact 2 were noted as having been extremely easy; all 3 were drained. It seemed that immediately after the operation was finished the temperature began to rise with an accompanying rapid pulse. Although no mention was made of liver traumatization, except in one instance, we believe that these patients died from absorption of either diseased or chemically altered liver cells, or toxic bile.

Payne, in an article recently read before the American Medical Association, endeavors to explain and to offer remedies for this bizarre complication. He states that if the common bile duct has not been drained it seems logical to fall back upon blood chemistry determinations of xanthoprotein, indican, and cholesterol esters. It has been shown that in severe liver damage and especially in hepatic coma xanthoprotein in the blood is high and blood indican low; this is different from the blood study of uremia where xanthoprotein is high and indican is high. He quotes Epstein as observing that in liver death there is marked lowering of the numerous relations between the cholesterol esters and the total blood cholesterol; also that a steady rise in cholesterol esters signified a favorable outcome.

The late Lord Moynihan reported a liver death which he felt followed ligation of a branch of the hepatic artery; ischemic necrosis of a large area of liver substance resulted; it was thus presumed that absorption of devitalized liver cells produced an overwhelming intoxication. There are many who have supported this view as the primary cause of all "liver deaths."

It has been demonstrated (18) experimentally in dogs that the clinical course of "liver death" and similar liver changes has followed ligation of the hepatic arteries; in the animals that did survive there was found adequate collateral circulation to all lobes of the liver, and absence of hepatic necrosis. Thus a pathologically descriptive term has been applied, "acute postoperative necrosis of the liver." From experimental investigation and from clinical studies (1), the following hypotheses have been offered:

in the "early" group it was only 4.8 per cent

Smith, some years previous to the publication of his paper in 1933, had no hesitancy in operating immediately, even though there was an elevation of temperature, and the patient was desperately ill. He changed his opinion rather abruptly following the death of an obese woman aged 53, upon whom a partial cholecystectomy during the acute stage had been done. In the records of the St. Luke's Hospital in New York, he found that 107 patients operated upon in the acute stage showed a mortality rate of 9.3 per cent while in a group of 94 patients who had been allowed to subside, 5 died with a 5.3 per cent mortality rate.

Recently a study of 300 consecutive cases of clinically acute cholecystitis was made by Pennoyer of our surgical staff at The Roosevelt Hospital. All of these patients had an elevation of temperature, abdominal pain, many of them had nausea and vomiting, accompanied by abdominal distention. All had rectal temperatures of 101 degrees or over with a leucocytosis of 12,000 or over.

His cases were selected as clinically acute ones to ascertain whether or not the management and the mortality rates were comparable to other groups studied. During this investigation he noted that only one half of the cases reported acute by the pathologist could be considered acute clinically. This was particularly noticed in the edematous, distended enlarged gall bladder with other signs of acute inflammation, where acute attacks were superimposed upon a chronic inflammatory process.

The most serious complication of acute cholecystitis is gangrene and perforation. I admit that it is much commoner than the textbooks of the older writers record but do not believe it is as frequent a complication as had been intimated recently, and consider it to be less serious than those which will ensue if cholecystectomy is to be performed routinely in the acute stage by the surgeon of average ability. Practically 90 per cent of patients acutely ill with clinical manifestations of acute cholecystitis will subside. It is striking to note the smooth convalescence of patients operated upon when gangrene, perforation and local

ized abscess have ensued. There were 30 deaths in The Roosevelt Hospital series of 300 consecutive cases—a mortality of 10 per cent. It is significant to note that half of these deaths occurred in the small group of 59 patients who were operated upon as emergencies. When the mortality rates are rearranged it is observed that immediate operation in our hands gives a mortality rate of 20 per cent while in the remaining group the rate is 5 per cent.

In 1926 the writer warned against the dangers of cholecystectomy too early in the acute stage. That paper was prompted by several deaths which were attributable to too rapid intervention. It was my belief at that time as it is now, that in the majority of these cases it is far better that these patients be observed for 24 or 36 hours, or even longer to see whether or not the temperature, pulse rate and blood count will diminish, indicating a subsidence of the inflammatory process.

When the temperature remains elevated after 36 or 48 hours, the pulse rapid and the general appearance is not improving, we do a cholecystectomy or a cholecystostomy. However, we are not by any means averse to immediate operation upon admission if the patient's condition indicates prompt intervention.

The 'delayed' treatment. Few surgeons consider it wise that surgery in all cases of acute cholecystitis be postponed, delayed or deferred until a complete remission has taken place weeks or even months later, thus watchfully waiting for an acute process to become a distinctly chronic one. I believe it is a common experience among surgeons that many patients will refuse operation after the subsidence of their acute symptoms. This is unavoidable and in many instances little harm has been done by the delay of months or even years.

Bruggeman has pleaded for more conservative treatment of acute cholecystitis yet even he could not be classified as a surgeon demanding a complete subsidence in all cases prior to operation. He quotes the opinion of many surgeons throughout our country and abroad who agree with his conservative stand. He mentions the names of Lewis, Archibald, Muller, Deaver, Haggard and certain German

ful individualization is necessary if operative mortality is to be kept low. Although there are a few surgeons who insist upon immediate operation after the patient has been admitted to the hospital, the great majority prefer to intervene in from 1 day to 5 days, thus allowing sufficient time for beneficial pre-operative measures to be instituted.

We have divided these surgeons into three groups: (1) those who operate immediately upon admission of the patient to the hospital; (2) early, 1 day to 5 days; (3) delayed (weeks or even months). The mortality rate in the hands of the majority of surgeons is better in the so called "early" group of operators than in the so called "immediate" group.

In our series of cases, convalescence following gangrene and perforation has been smoother and more satisfactory than is usually stated by most authors.

The treatment of acute cholecystitis cannot be compared with the treatment of acute appendicitis. The exact cause of liver death and shock is unknown. Suggested causes are: intoxication due to the absorption of devitalized liver cells, disturbed liver metabolism and dysfunction, hidden infections.

Meticulous pre-operative study of the blood chemistry and the study of the bile if the ducts are drained will lower the mortality.

CONCLUSIONS

1. The majority of surgeons are obtaining better results by waiting from 1 to 5 days before operating upon patients suffering from acute cholecystitis. Time is thus given for the acute inflammatory process to subside and the patient offered the opportunity to be properly

prepared for the shock of a major surgical procedure.

2. The mortality rate will be higher in the hands of the majority of surgeons if "immediate" operation in all cases is advised.

3. More frequent and painstaking post-mortem examinations would no doubt throw light on the cause of "liver shock and deaths."

1 A sudden release of biliary obstruction, rather than obstruction itself, is responsible for the fatal outcome in certain cases of biliary tract surgery

2 Liver changes already present in biliary tract disease are aggravated at times by operative measures which are supposed to relieve it, and thus there is released a toxic substance into the circulation which is presumed to be a water soluble foreign protein

3 When the function of the liver is stopped the kidney takes up the process of detoxication from which results damage to the convoluted tubules through which foreign proteins are excreted

4 The liver-kidney syndrome is a single pathological process of which the kidney pathology represents the second stage

Due to repeated failure at autopsy to find sufficient liver pathology to explain these repeated deaths, it has been suggested (5) that the fatal syndrome is not hepatic but extrahepatic with possibly an important cerebral factor so that careful postmortem examination of the brain should be insisted upon

Tourof has attempted to show that virulent infection may produce a chemical syndrome identical with so called "liver shock." He believes that often the infection is incapable of being detected, the patients being so ill that it is difficult for the examiner to determine the presence of any positive physical signs. He showed that often postmortem examination failed to reveal patients dying of so called "liver shock" but really succumbing to other complications

With the newer methods of determining liver function before operation some idea should be obtained as to whether or not this viscus can be held partially or completely responsible for the fatalities. The mortality following cholecystectomy due to liver dysfunction can thus no doubt be lowered by the more painstaking selection of cases

In jaundice, dye tests are of value in determining the activity of liver parenchyma and should be undertaken before operation in all such cases. Today, surgeons appreciate too infrequently the danger of the acute toxic liver incompetence which sometimes follows operative measures and which occasionally

results fatally. Whether the cause of these startling deaths is hidden infections, chemically altered liver cells, disturbed liver metabolism or liver dysfunction, meticulous preoperative data can and should be obtained

Pre operative management A satisfactory pre-operative program cannot be carried out with those patients who of necessity must undergo immediate operation. However in cases in which it is safe to allow the symptoms to subside and to plan interference some 4 to 6 days later it is of value

1 To know of upper respiratory infections and to treat them if they exist

2 To obtain thorough cleansing of the lower intestinal tract

3 To institute a minute laboratory investigation, with a complete blood count, blood chemistry studies, xanthoprotein, indican, and cholesterol esters determination. If the urea nitrogen is not within normal limits the liberal use of fluids is indicated. The blood sugar should be carefully noted. The sedimentation rate gives some index of liver damage, if elevated the liberal use of glucose insures glycogen store. The icteric index is a source of information as to blockage of the ducts, slight elevation of from 15 to 20 probably means a cholangitis or liver damage. Roentgen ray vision with dye is valueless if the patient is jaundiced and there is known to be liver damage, it is of doubtful value in the face of irritations of the gastro intestinal tract, such as peptic ulcer, acute appendicitis or malignancy

4 To give intravenous infusions of 1,000 cubic centimeters of 5 per cent glucose in saline twice daily, a diet high in carbohydrates and low in fats is recommended. Transfusions of blood are given to the jaundiced patient prior to, and immediately following operation, especially if there is profuse bleeding or a prolonged operating time. Liver function tests, though properly administered, often give but scant information, therefore, saturation with water and sugar should be given intravenously before and after any operative maneuver on the biliary tract

SUMMARY

No set time is feasible for surgical interference in all cases of acute cholecystitis. Care

Fig 1 Various stages in the formation of a diverticulum; a, left, early stage, b, center, later stage, c, right, final stage,

showing how thinning of the muscular layer over the surface of the diverticulum takes place

gested that perhaps the dragging effect of the vessels supplying blood to the bowel produces diverticula

Our observations have led us to the belief that acquired diverticula originate, as both Edwards and Fraser have stated, in close proximity to the vascular supply of the intestine (Fig. 1). According to Butler, the pull of the vasa recti of the superior mesenteric artery as a result of sclerosis is probably an important factor in the formation of intra-mesenteric diverticula of the small intestine

C. H. Mayo once saw a diverticulum form during the course of an intestinal operation. It occurred on the mesenteric border of the sigmoid at a time when the proximal segment of bowel was in a state of contraction.

DIAGNOSIS AND TREATMENT

Duodenal diverticula. Of the diverticula of the intestine, about 18 per cent (Fig. 2) have as their site of origin the duodenum and they are present most often in individuals 50 years or more of age. Frequently, duodenal diver-

DIVERTICULA of the intestine, when they are symptomless, may be considered as nothing more than anatomical curiosities. Such sacculations or pouches, however, may become the sites of an inflammatory process, or neoplastic changes may occur in them. The development of either of these conditions may produce symptoms requiring medical treatment or surgical intervention.

Some diverticula are congenital in origin (for example, Meckel's diverticulum), but the majority are thought to be acquired. It is quite logical therefore that inquiry should be made to learn the reason for their formation. Virchow, for example, described diverticula of the small intestine as herniations of the mucosa through the muscular layers of the intestinal wall. Edwards, in an extensive review of the literature on jejunal diverticula, together with a report of his own cases, emphasized the point that diverticula apparently invariably form in close proximity to the small vessels supplying the intestinal wall. He called attention to the fact that, usually, blood is supplied to the intestine by pairs of vessels. In confirmation of his theory as to the origin of diverticula, Edwards illustrated his paper with specimens and diagrams which showed diverticula arising in pairs corresponding to the points where the paired blood vessels entered the intestinal wall. He expressed the opinion that as the diverticula increase in size they encroach on one another and produce pressure on the mesial wall, with the end result that they become converted into a single diverticulum. Further evidence that diverticula originate at the point of entrance of blood vessels into the wall of the intestine is found in the fact that the majority of diverticula arise from the mesenteric side of the bowel.

Careful microscopic study of intestinal diverticula reveals for the most part a characteristic picture. It will be seen that the mucosa has herniated through the wall of the intestine and in some instances that the muscular layers cover a portion of the diverticulum. Near the base of the pouch the muscular structure is highly thickened, at the apex it is thinned out. Edwards also called attention to the almost valve like muscular apparatus at the mouth of the herniation.

THE MECHANISM BY WHICH INTESTINAL DIVERTICULA ARE FORMED

When contraction of the intestine occurs, it is obvious that the openings for the entrance of blood vessels become smaller in the contracting segment of the intestine while, in the relaxed portion, there is a tendency for such openings to become larger. If contractions occur when a relaxed segment of intestine is between two contracting portions, the pressure exerted on the relaxed segment where the vascular openings are larger may be sufficiently great to cause herniation. Most observers share this view regarding the causation or formation of diverticula. Some believe that the areas of decreased resistance in the wall of the bowel are produced by degeneration of the venous connective tissue, and that increased pressure within the intestine may cause the formation of diverticula through such areas. Sudsuki, particularly, has voiced this view. Fisher suggested that thinning of the circular muscular layer may occur and that, when this happens, an evagination of the mucous membrane may quite easily find its way through the longitudinal muscular layer to the serosal coat, forming a diverticulum. Fisher has also observed definite thickening of the peritoneal layer covering a diverticulum, thus is apparently an attempt to limit the process. Klebs has observed that some segments of bowel containing diverticula have an extremely short mesentery, and he sug-

usually symptomless. Occasionally, however, duodenal diverticula become large enough to produce symptoms of partial obstruction mechanically, in which event surgical intervention is indicated. The operative procedure of choice in such cases is dependent on certain factors in the individual case, the procedure most commonly undertaken being removal or inversion. It is quite obvious that the latter operation should be carried out only when the diverticulum is small.

The diagnosis of duodenal diverticula is not made clinically, and it is strictly roentgenologic when it is made before operation or

before necropsy. Since duodenal diverticula are often quite large, the characteristic extraluminal outpouching is usually recognized without difficulty as the opaque meal is followed along the course of the duodenum after it has passed through the pylorus. Figure 3 represents a typical instance. The patient was a man, aged 71 years, who for 20 years had complained occasionally of a sensation of fullness and bloating in the epigastric region after eating. His symptoms, plus the finding of a duodenal diverticulum, were not thought sufficient, however, to warrant surgical intervention.

Fig. 4 Multiple duodenal and jejunal diverticula

Fig. 5 Meckel's diverticulum of ileum

ticulum and duodenal ulcer are concomitant findings. Moynihan, however, said that these duodenal sacculations are not true diverticula but "pouchings" and that they were not related to true diverticula. So far as we know, it is impossible to say whether diverticula are more frequent in cases in which ulcer is pres-

ent, but if the diverticula are more prevalent in individuals who have ulcer, apparently the occurrence has not been explained. Possibly if the irritating cause is sufficient, contractions occur in another portion of duodenum synchronously, thereby producing herniation in the segment which is not undergoing spasm or contraction. The most frequent site of duodenal diverticula is near the ampulla of Vater. Even when large, such diverticula are

His symptoms, plus the finding of a duodenal diverticulum, were not thought sufficient, however, to warrant surgical intervention.

Fig 7 a left Diverticulitis of descending colon and b right carcinoma of descending colon, showing typical roent

Jejunal diverticula Hanseemann described a case in which, at necropsy, more than 400 diverticula were found in the jejunum. About 6 per cent of intestinal diverticula occur in this segment of the intestine, and as a rule, multiple diverticula will be found. Of 4,820 necropsies, 9 revealed jejunal diverticula. In many cases in which jejunal diverticula develop, the patients complain of gaseous rumbling in the upper left abdominal quadrant after meals; others experience intermittent cramping abdominal pain following the ingestion of food. In a few cases vomiting and diarrhea occur. The diagnosis of jejunal diverticulum is likewise chiefly a roentgenologic problem. Diverticula in this portion are also large and are generally recognized with ease as the opaque meal is observed to pass through these segments. As a rule the diverticulum does not evacuate the contrast substance readily, and the outpouching is readily

recognized even after the lumen in the immediate vicinity has contracted and propelled all but a very small residue of the opaque substance from the mucosal folds.

When surgical treatment is considered advisable, removal of the diverticulum or diverticula is carried out. If many herniations are present, then resection of the involved segment is the procedure of choice. Figure 4 shows many diverticula in the jejunum of a patient, aged 71 years, who did not give a history of any intestinal disorder save an occasional attack of diarrhea in the previous 10 years. Surgical intervention was thought to be inadvisable.

Diverticula of the ileum Only about 15 per cent of acquired intestinal diverticula occur in the ileum. Some cases of ileal diverticula have been reported in which the herniation arose from the mesenteric border. Most ileal diverticula, however, are congenital and

since Meckel's diverticulum is quite a common finding, the discussion will be limited to it. It is thought that Meckel's diverticulum is present in 2 per cent of all individuals.

The existence of Meckel's diverticulum may be suspected, but the diagnosis has seldom been made before operation. In several cases in which we have strongly suspected the presence of inflammation or disease in a Meckel's diverticulum, exploratory operation substantiated our preoperative impression. Persistent bleeding from the rectum in children is always suggestive of the presence of a Meckel's diverticulum. Also, attacks of cramp-like pain in the region of the umbilicus are often indicative of it. A few Meckel's diverticula have been found at operation in which the neck of the lumen was quite small and was the cause of complete or almost complete obstruction of the diverticulum, a condition somewhat analogous to that of the appendix in appendicitis. The presence of gastric mucosa in diverticula of the Meckel type is responsible for many of the ulcers that have been observed in these pouches, and it undoubtedly accounts for many of the symptoms. Gray and Kernohan have reported a case in which there was malignant degeneration of the gastric mucosa in a Meckel's diverticulum; microscopic study of the malignant process revealed a structure similar to that of gastric carcinoma. In 2 cases in which the heterotopic gastric mucosa in such diverticula had undergone ulceration, the patient observed that his pain ceased 2 or 3 hours after the ingestion of food. Pancreatic tissue has also been found in diverticula of the Meckel type.

Case was the first to demonstrate Meckel's diverticulum by the use of roentgen rays, many years elapsed before another instance was reported in the roentgenologic literature. Then others, among them Pfahler, Allemann, and Prévôt, reported other cases. Up to the present time Meckel's diverticula have been demonstrated roentgenologically on but 3 occasions at The Mayo Clinic. Since these diverticula vary so widely in their gross morphologic characteristics, a typical roentgenologic appearance is not to be described. The roentgenologic appearance may, how-

Fig. 8 Diverticulosis of colon.

ever, be expected to reflect the morphologic contour of the particular diverticulum. Figure 5 a and b illustrates this point in a satisfactory manner. The patient, a man 39 years of age, had had gaseous eructations for 10 years, and during the past year there had been knife-like pain and tarry stools. Marked ileitis was responsible for his symptoms and on this account 35 centimeters of ileum and colon were removed. However, a Meckel's diverticulum was also present and gave a typical roentgenographic manifestation.

In another case, a girl aged 5 years, blood had been passed by rectum on several occasions. In the 3 years prior to her examination at the clinic she had had attacks of diffuse, cramp-like abdominal pain. She also had severe asthma. On examination she appeared to be somewhat cachectic. There was marked secondary anemia. Abdominal exploration

Fig 7 a left Diverticulitis of descending colon and b right carcinoma of descending colon showing typical roentgenographic finding for both types of lesions

Jejunal diverticula Hanseemann described a case in which, at necropsy, more than 400 diverticula were found in the jejunum. About 6 per cent of intestinal diverticula occur in this segment of the intestine, and as a rule, multiple diverticula will be found. Of 4,820 necropsies, 9 revealed jejunal diverticula. In many cases in which jejunal diverticula develop, the patients complain of gaseous rumbling in the upper left abdominal quadrant after meals, others experience intermittent cramping abdominal pain following the ingestion of food. In a few cases vomiting and diarrhea occur. The diagnosis of jejunal diverticulum is likewise chiefly a roentgenologic problem. Diverticula in this portion are also large, and are generally recognized with ease as the opaque meal is observed to pass through these segments. As a rule the diverticulum does not evacuate the contrast substance rapidly, and the outpouching is readily

recognized even after the lumen in the immediate vicinity has contracted and propelled all but a very small residue of the opaque substance from the mucosal folds.

When surgical treatment is considered advisable, removal of the diverticulum or diverticula is carried out. If many herniations are present, then resection of the involved segment is the procedure of choice. Figure 4 shows many diverticula in the jejunum of a patient aged 71 years, who did not give a history of any intestinal disorder save an occasional attack of diarrhea in the previous 10 years. Surgical intervention was thought to be inadvisable.

Diverticula of the ileum Only about 1.5 per cent of acquired intestinal diverticula occur in the ileum. Some cases of ileal diverticula have been reported in which the herniation arose from the mesenteric border. Most ileal diverticula, however, are congenital, and

Carcinoma and diverticulitis may be co-existing conditions but there is no reason to believe that diverticulitis is a precursor of malignancy. The clinical differentiation between diverticulitis and malignancy of the colon is frequently difficult to make. The symptoms of an acute inflammatory process are, of course, in favor of a benign condition. The passage of a large amount of blood and mucus with the stool is one of the predominant symptoms of malignancy. Bagen and Dixon reviewed a large series of cases of diverticulitis and observed that noticeable bleeding by rectum was quite a rare symptom of that condition. A review of the differential roentgenologic diagnostic criteria has been made previously (5). It was pointed out that accurate differential diagnosis between these conditions is possible at the roentgenologic examination. Figure 7 a and b shows the typical roentgenographic manifestations of carcinoma (left) and diverticulitis (right). Both of these lesions are in the descending colon at the crest of the ilium.

The treatment of diverticulitis of the colon in its earlier stages is not a surgical problem. Even if there is marked deformity of the bowel due to diverticulitis, rest in bed, a non-residue type of diet, liberal doses of belladonna, and warm saline irrigations by rectum, frequently cause the process to subside. With care of the diet such individuals may continue throughout life with nothing more serious than an occasional attack. Figure 8 shows multiple diverticula throughout the colon of a man aged 89 who succumbed to a cerebral accident. Throughout life he gave no history of any intestinal disturbance. Figure 9 a and b shows roentgenograms of the colon before and after medical treatment of diverticulitis.

There are other cases in which the condition is intractable to all forms of medical management and operation obviously is indicated. It has been our plan to manage stricture formation surgically by establishment of a colonic stoma in an uninvolved portion of the

bowel proximal to the involved segment. The establishment of such an artificial anus frequently allows the inflammatory process to subside completely and closure of the colonic stoma can be carried out with good results subsequently. Judd was of the opinion that such colonic stomas should not be closed before a year had elapsed.

If it is obvious that more radical treatment for diverticulitis is required, the next surgical procedure to be considered is resection of the involved segment, and even this should sometimes be antedated by colostomy, particularly if there is abscess formation or perforation into an adjacent viscus such as the urinary bladder.

Fig 9 Diverticulitis of sigmoid a left roentgenogram before medical treatment February 3 1934 b right after patient received medical treatment February 12 1934

disclosed a Meckel's diverticulum, 66 centimeters in length in the distal portion of which there was marked ulceration (Fig 6). The ileum and the diverticulum had a common mesentery, and removal without sacrifice of the ileum was therefore impossible. It was felt that the symptoms might abate if treatment similar to that for some peptic ulcers were employed, and for that reason an anastomosis was made between the ileum and the diverticulum. Unfortunately, however the patient succumbed to bronchopneumonia a few days following operation.

It must be admitted that in the past, roentgenologic examination seemed to have little to offer in the diagnosis of this condition. It may be predicted, however that the roentgenologic diagnosis of Meckel's diverticula will become more and more satisfactory as roentgenologic experience with them accumulates. Such Meckel's diverticula as are small and communicate with the lumen of the bowel by a very wide neck will, however, be recognized roentgenologically only with the greatest difficulty, and in a certain number of the

cases will inevitably escape roentgenologic detection.

Diverticula of the colon By far the majority of diverticula (about 60 per cent) occur in the sigmoid, some have stated that as high as 80 per cent of colonic diverticula occur in the lower part of the descending colon and sigmoid. The condition in which one or more diverticula have been formed is known as "diverticulosis."

The term "diverticulitis" is applied to that state in which one or more of the diverticula have become inflamed. It has been estimated that in about a fifth of people with diverticulosis, diverticulitis develops. The complications and sequelae of diverticulitis are stricture formation, perforation with abscess formation, or perforation into or onto another viscus, peritonitis and fistula. The symptoms of acute diverticulitis are similar to those of acute appendicitis except, of course that in the former the symptoms are confined to the left lower quadrant of the abdomen. About 33 per cent of patients with diverticulitis have a palpable mass in that region.

effect, however, is a great slowing of the heart rate. When the abdominal muscles relax, the intra-abdominal pressure falls, and the excessive quantity of blood which has been forced into the chest flows back out of it. Thus over-dilatation of the heart is prevented. If vomiting occurs after the vagi have been cut, it is accompanied by a great rise of blood pressure.

Is the intra-abdominal circulation impeded when the intra-abdominal pressure is greatly increased by ascites, by the pregnant uterus, or by tumors? The abdominal veins have walls of paper thinness which are easily compressed by the slightest pressure. It would seem that they would be blocked when the intra-abdominal pressure is elevated, but every day experience shows that they are not, and that the blood flow through the abdominal viscera is not stopped by even an enormous increase in the intra-abdominal pressure. The question is answered by the results of the following experiment:

Arrangements are made to record the systolic blood pressure, the intra-abdominal pressure, and the pressure in the vena cava. The intra-abdominal pressure is then elevated by injecting normal salt solution into the peritoneal cavity. As the intra-abdominal pressure increases, the pressure in the vena cava increases, and the two are always equal. When the intra-abdominal pressure equals the systolic blood pressure, all flow through the abdominal organs ceases, and they are white and bloodless.

From this experiment we conclude (1) that the heart forces enough blood through the capillaries to maintain an intravenous pressure equal to the intra-abdominal pressure; (2) that the intra-abdominal circulation cannot be stopped by any increase in intra-abdominal pressure lower than the diastolic blood pressure.

The second conclusion requires comment. When the pressure upon a capillary equals the diastolic blood pressure, the flow of blood through it occurs only in systole when the arterial pressure rises above the diastolic pressure. The flow, therefore, consists of a series of brief spurts. As we shall show later, the resulting volume of blood flow is insufficient to maintain the normal activities of the tissues.

It has been shown experimentally that when salt solution is injected into the peritoneal cavity in sufficient quantity to increase the intra-abdominal pressure to equality with the diastolic blood pressure, the absorption of the salt solution is very slow (10).

In the experiment just described, sudden removal of the fluid caused no noteworthy change in the blood pressure. The collapse of the patients who, while in the sitting position, have had large amounts of ascitic fluid removed, is to be attributed for the most part to the inability of the overstretched abdominal walls to compress the great capillary and venous reservoir of the abdomen sufficiently to provide an adequate supply of blood to the heart. Of course, a vasomotor relaxation within the abdominal viscera would hasten the onset of this difficulty, which is not likely to occur if the patient is kept in the recumbent or head-down position.

The venous return from the lower extremities is not prevented by increased intra-abdominal pressure as long as the valves in their veins are intact. If the femoral vein be tied and cut just below Poupart's ligament, it will be found that the venous pressure in its distal portion, as measured with a mercury manometer, is equal to the systolic blood pressure. It may be increased until it is several times greater than this by compression of the leg. The valves in the leg veins give them the power of a force pump, so that contraction of the leg muscles around the veins raises the intravenous pressure to any height necessary to force the blood from the femoral into the iliac veins.

DISTURBANCES OF CIRCULATION LIMITED TO SINGLE ABDOMINAL ORGANS

Distention and venous obstruction are the common causes of circulatory disturbance in the hollow, distensible abdominal organs. Venous obstruction affects chiefly those organs having a mesentery.

Effects of distention. These can be produced and studied most conveniently in the wall of the intestine. Facts established by this study apply in general to the circulation of any hollow, distensible viscus. The set-up for this study is shown diagrammatically in Figure 1.

DISTURBANCES OF THE BLOOD AND LYMPH CIRCULATION OF THE ABDOMEN

W D GATCH M D F A C S, Indianapolis Indiana

THIS paper covers only those disturbances of the abdominal circulation which are peculiar to it. Disturbances due to embolism, thrombosis, arterial disease, and cardiac failure are not within its scope. It deals chiefly with acute derangements of circulation such as may occur in fairly healthy patients who require operation. These may affect the entire abdominal circulation or they may be limited to the circulation of a single organ.

DISTURBANCES OF THE ABDOMINAL CIRCULATION AS A WHOLE

The abdominal vessels have two important functions beside supplying blood to the abdominal organs. They serve as a reservoir to regulate the flow of blood in the lesser circulation. Some of them, in the liver and spleen, constitute a wonderfully efficient apparatus to remove bacteria and other particulate matter from the blood.

Disturbances of the flow of blood from abdomen to thorax. The great capacity of the abdominal vessels is obviously of advantage at times to the entire circulation, because it permits the temporary storage of blood in the abdominal organs when, for any reason, the supply of blood to the heart is greater than it can pump. The quantity of blood in the abdomen varies between wide limits. In man after fasting it probably does not exceed 25 per cent of the total blood volume. It is possible to impound

in the abdomen of a dog nearly all the blood in its body.¹

The absence of valves in the abdominal veins permits a rapid backflow into them of blood accumulated in the thorax. In the course of general anesthesia, the head down position or vigorous struggling may prevent this unloading of the thoracic veins, and thereby imperil life. This danger is not great unless the air way is obstructed. Then a high negative pressure in the chest accelerates the flow of blood from abdomen to thorax. This over dilates the heart when it is suffering from anoxemia. Experiments show that this evil combination may damage a normal heart beyond recovery in a time as short as 2 minutes (7).

Failure of a normal quantity of blood to leave the abdomen is present when the abdominal muscles are paralyzed and the patient put in the erect posture. Thus a deeply anesthetized animal dies if kept in the head up position because of the accumulation of blood in the abdomen. Patients with paralyzed abdominal muscles cannot remain upright for any considerable time. It would seem that compression of the abdominal viscera by the muscles which enclose them is essential to the maintenance of the circulation under the ordinary conditions of life (6).

Ejection of the stomach contents by vomiting is accomplished by powerful compression of the stomach by simultaneous contractions of all the muscles which enclose the abdomen. This expels from the abdomen not only the contents of the stomach but a large quantity of blood as well, the blood being forced through the inferior vena cava into the right chambers of the heart. Nature has evolved a remarkable adaptation to protect the heart in this event. During vomiting there is a vagal inhibition of the heart. This may cause the blood pressure to fall to zero because of a complete cessation of heart action. The usual

Presented before the Clinical Congress of the American College of Surgeons, Chicago, October 25-29, 1927.

Two determinations of the quantity of blood in the abdomen of the fasting dog were made. The total blood volume was determined by the dye method. The dog was then killed instantly with cyanide and its aorta, axillary veins, vena cava ascending and common iliac vessels were clamped. All blood was then expelled from the abdominal viscera by forcing first physiological salt solution and then air into the aorta. The escaping fluid was collected from the vena cava. Sections of the viscera after this showed them to be bloodless. In one experiment 10 per cent and in the other 25 per cent of the total blood volume was obtained. In the human the quantity of blood in the abdomen (after fasting) is probably somewhat greater, possibly 25 per cent. For the effect of food on the blood flow of the digestive organs see Mann (9).

found that various sugars pass through the living bowel at fixed rates which are different for each sugar. In about 6 hours they all begin to pass through more rapidly and at the same rate. Six hours is therefore a fairly accurate estimate of the survival time of the detached bowel.

Both types of experiment show that the bowel can endure a remarkably long period of anemia. Under clinical conditions the intestine may not be injured beyond recovery by several days of distention. This is because the distention is usually intermittent. It is probable, however, that distention may injure the intestinal mucosa enough to deprive it of power to keep toxic substances, always present in the bowel lumen, out of the blood. Even in this event, the body is protected from harmful absorption by way of the mesenteric veins if the bowel is distended by a force equal to the diastolic blood pressure. Patients suffering from advanced bowel obstruction may have a very low diastolic blood pressure, which can easily be equalled by the intra-intestinal pressure.¹ If the latter be suddenly reduced, the circulation through the bowel will be restored and the absorption of toxic material will occur.

A probable explanation of death following shortly after the release of a bowel obstruction is that the operative trauma causes an overwhelming absorption of toxic material both by the mesenteric and by the transperitoneal route. Weatherby and Chen have shown that toxic material can pass through the entire wall of the partially devitalized bowel. It has been demonstrated that the inflammatory exudate thrown out by the peritoneum about the damaged bowel hinders the absorption of toxic material which has passed through the bowel wall. It is easily conceivable that the removal of this exudate over long reaches of bowel may lead to the absorption of a fatal dose of toxins (10). Toxins absorbed by way of the mesentery pass through the liver, which has a well known detoxifying action; those absorbed by the transperitoneal route pass directly into the systemic circulation.

It is certain that by gradual deflation of the

¹Since the function of the bowel is carried on in a fairly normal manner as long as the intra-intestinal pressure does not exceed the diastolic blood pressure, it is probable that the bowel mucosa will not be injured enough to permit the passage of toxins unless the intra-intestinal pressure equals the diastolic blood pressure.

bowel and relief of dehydration before operation, the death rate from advanced bowel obstruction can be greatly reduced.

Effects of distention on hollow viscera other than the bowel. The effects of distention on the appendix and cystic ovary are much the same as on the intestine. The effects on the gall bladder are peculiar and call for special comment.

Distention of the gall bladder. If the cystic duct of an experimental animal be tied, the gall bladder will be found, after a few hours, to be contracted. If the common duct be tied and the cystic duct left open, then the gall bladder becomes greatly distended (13, 16). In the former case the gall bladder remains contracted because of the rapid absorption of water from its contents. In the latter case it becomes distended because its power of abstracting water from its contents is not sufficient to cope with the constant arrival of more fluid by way of the cystic duct.

When this condition exists in the human subject, due to obstruction of the common bile duct by cancer, the gall bladder distends to five or six times its normal size, but rarely or never becomes gangrenous. The pressure within it, probably from 250 to 300 millimeters of water (14), is too low to cause a dangerous impairment of circulation. The gall bladders dealt with by the surgeon are usually without function, which means that they have little or no power to absorb water from their contents. A gall bladder in this condition may become distended to a great size. In one observed by the writer the distention was intermittent and apparently due to the presence of a ball valve stone in the cystic duct. Here the gradual stretching of the gall bladder permitted the maintenance of the circulation. Massive gangrene of the gall bladder and appendix cannot be explained by distention, but is probably always due to venous obstruction.

Effects of venous obstruction. In the intestinal preparation we have described, if a manometer be tied into the vein draining the closed piece of bowel, the venous pressure, as measured by the manometer, will be seen to rise until it equals the systolic blood pressure. This is proof that the systolic blood pressure in the presence of venous obstruction is trans-

Fig. 1 Diagram showing set up used in study

By means of this preparation and modifications of it we can show

1 That the venous outflow from a distended bowel decreases as the intra intestinal pressure increases, and ceases when the intestinal pressure equals the systolic blood pressure¹

2 That distention of the bowel causes no venous congestion thereof This can be demonstrated easily by measuring the venous pressure in a branch of the outflowing vein when the latter is not obstructed I mention this to disprove the idea, which appears in the literature, that distention of the bowel causes a venous congestion of it

3 That the bowel is in no way injured by an intra intestinal pressure short of that necessary to rupture it, provided the pressure is present for a short time only After deflation the bowel can be made to contract normally, and, on microscopic study of its wall, no damage thereto can be observed

4 That the function of the bowel as shown by its power of absorption is carried on in a

1. A rest of the blood flow by distention, which is attributed to the negative pressure in the lumen of the intestine. This is not true as the pressure is shown by a manometer in the dilated bowel when its artery is filled with blood. The artery of all the bowels is a part of the arterial system, and it is not possible to distend the organ, they supply. The rest of blood is due to compression of the capillaries.

fairly normal manner in the presence of intra intestinal pressure lower than the diastolic blood pressure, but that all absorption except by the transperitoneal route ceases when the pressure is higher than this²

5 That distention of the bowel causes no edema of its wall, and diminishes or abolishes secretion by its mucosa. The bowel, when tightly distended, becomes covered by drops of fluid, it is true, but these are composed of plasma squeezed from the tissues

6 That tightly distended loops of bowel kept for a number of hours in the abdomen gradually increase in diameter and may remain viable provided the pressure within them does not increase as fast as their walls are stretched. The enlargement of the bowel under these conditions diminishes the pressure on the capillaries of its wall and permits a resumption of the blood flow

The effects of anemia on the bowel wall can be studied also by experiments on pieces of fresh, detached rabbit intestine. By this means we can determine how long the totally anemic bowel can survive. This determination was made at my request first by Dr. J. H. Weatherby and later by Dr. K. K. Chen (10). The bowel was assumed to be alive as long as its power of selective absorption was not completely lost. The normal bowel will not absorb histamine, proteoses, and peptones. It absorbs sugars at a definite rate.

The experiment was performed by immersing closed pieces of fresh intestine, containing one or more of these substances in Ringer's solution. The latter was tested at frequent intervals for the material in the bowel.

Chen found that pure peptone will not diffuse through the bowel wall in 24 hours. He found that histamine begins to diffuse in about an hour, its passage being slow until after the sixth hour when it rather suddenly begins to pass through at a greatly increased rate. He

1. A number of dogs we tested the effect of distention upon the rate of passage of a piece of bowel several feet in length we applied a ligature to the middle. We inflated it with a piece of bowel it excluded but not the other. In an experiment I did we obtained more than a man's quantity of fluid in the distended piece of bowel. We then removed the ligature and the fluid was absorbed. We always obtained a small but measurable amount of fluid from the distended piece of bowel. The pressure was maintained from half the diastolic blood pressure to the systolic pressure. This was the reason for the distention of the bowel. It is well known that the passage of fluid into the bowel is determined by the pressure of the blood in the arteries of the bowel.

found that various sugars pass through the living bowel at fixed rates which are different for each sugar. In about 6 hours they all begin to pass through more rapidly and at the same rate. Six hours is therefore a fairly accurate estimate of the survival time of the detached bowel.

Both types of experiment show that the bowel can endure a remarkably long period of anemia. Under clinical conditions the intestine may not be injured beyond recovery by several days of distention. This is because the distention is usually intermittent. It is probable, however, that distention may injure the intestinal mucosa enough to deprive it of power to keep toxic substances, always present in the bowel lumen, out of the blood. This is proof that the systolic blood pressure in the presence of venous obstruction is trans-

Fig. 2. Diagram to illustrate the interchange of materials through the capillary wall. *C*, blood capillary; *L*, lymph capillary; *TS*, tissue spaces around both.

mitted through the capillaries into the vein. Under these conditions the bowel soon becomes thick and sodden with extravasated blood. Its mucosa becomes detached and all its tissues disorganized. This is because of rupture of the capillaries by a pressure they are not able to withstand. This mechanism is the most common cause of disturbances of the circulation of individual abdominal organs. It is present when a loop of bowel passes into the neck of a hernial sac or beneath a peritoneal band. It is present in volvulus of the bowel and in rotation of an ovarian cyst on its pedicle. In all these cases the thin wall of the vein is compressed, whereas the artery is not, so that it continues to pour blood into the tissues. Early gangrene is the result. Distention of a hollow viscus may protect its capillaries from the disastrous effects of venous obstruction.

EXPLANATION OF OBSERVATIONS

The explanation of the foregoing observations is to be sought in the laws which govern the capillary blood flow and the interchange of materials through the capillary wall.

The discovery by Starling (17) that the blood proteins produce a measurable osmotic pressure, permitted him to formulate his theory, now generally accepted, on the interchange of water and other materials between the blood and lymph. This has been of great help to clinical medicine—for example in the explanation and treatment of edema and surgical shock. Krogh expresses the present day opinion of physiologists when he points

out that the interchanges under consideration can be explained as due to an interplay of filtration and osmotic pressures, without invoking the aid of a mysterious, vital secretory action by the thin endothelial cells of the blood and lymph capillaries. This matter can be most easily explained by means of the diagram, Figure 2, which shows the following: *C* is a blood capillary, *L* a lymph capillary, *TS* tissue spaces around both. The wall of *C* is easily permeable to water and soluble material and almost impermeable to proteins. The wall of *L* is permeable not only to water and soluble material but to proteins and particulate matter as well. The blood pressure in *C* tends to force water into *TS*. The osmotic pull of the proteins in *C* opposes this filtration and tends to draw water from *TS* into *C*. In the arterial end of *C* the filtration pressure is greater than the osmotic pull, and water passes into *TS*. At the venous end of *C*, the osmotic pull exceeds the filtration pressure, and water passes into *C*. Soluble materials in *TS* and *C* diffuse so readily through the wall of *C* that they can exert at most only a temporary effect on the passage of water.

The passage of water back and forth through the wall of *C* is influenced by osmotic and mechanical pressures in *TS*. The osmotic pressure in *TS* favors the outward passage of water from *C* and hinders its inward passage, while the mechanical pressure in *TS* has the contrary effects.

While these pressures in *TS* under normal conditions are relatively unimportant, they are all important in the derangements of circulation we have been describing. Thus, when the bowel is inflated, the stretching of its wall raises the mechanical pressure in *TS*. It is evident that as this increases, the blood flowing through *C* will decrease and cease to flow continuously when *TS* equals the diastolic blood pressure. It is evident also that elevation of the pressure in *TS* will diminish or abolish filtration of water from *C*, and that it will not injure *C* unless it is great enough to tear the tissues asunder. The effects of elevating the pressure in *TS* upon the function of the tissues are exactly what would be expected. When the pressure in *C* is elevated by venous obstruction to the level of the systolic blood

pressure, it is evident that the rupture of *C* is inevitable. Since the intracapillary pressure rises as the venous pressure rises, there can be no absorption of water by the capillary in the presence of a certain low degree of venous obstruction.

DISTURBANCES OF THE ABDOMINAL LYMPHATIC CIRCULATION

It is clear that disturbances of the blood flow, which we have been discussing, are always accompanied by disturbances of lymph flow. Thus, elevation of the intra-intestinal pressure beyond a certain height will abolish the flow of lymph in the abdominal wall; a slight rise in intravenous pressure will increase the flow of lymph, while complete venous obstruction will abolish it.

The clinical literature on the abdominal lymphatics has dealt almost entirely with means of preventing the absorption of toxic material by them. In the early days of abdominal surgery, there was a great fear of the escape of bacteria and toxins from the peritoneal cavity by way of lymph vessels. This was due to the idea that the peritoneal cavity is an immense lymph space, draining freely through openings in the peritoneum of the diaphragm into thoracic lymph vessels. The Fowler position was supposed to retard this drainage. Histological study has shown, however, that no openings through the peritoneum exist, that its mesothelium is everywhere continuous, and that it is not a part of the lymphatic system (2, 12). Furthermore, studies on absorption from the peritoneal cavity have shown that it is chiefly by way of the blood vessels (3). These absorb water and solutes, and apparently may take up bacteria and other small solid particles. The lymphatics take up only proteins and solid particles. Many solid particles, however, do not leave the peritoneal cavity, but are fixed *in situ* by exudate (10). Moreover, both clinical and experimental observations show that absorption from the inflamed peritoneum is very slow. "This fact," says Hertzler, "is self-evident, for the result of reaction to irritation is exudation, not absorption." David and Sparks have shown that the protective action of peritoneal exudates is very efficient. Every

day clinical experience supports this conclusion.

It seems to me that the evidence indicates that there are two more or less separate systems of lymphatics in the abdomen. The first of these supplies the gastro-intestinal canal and its accessory glands. It drains directly into the thoracic duct. The lymph in the thoracic duct comes chiefly from these lymphatics. It carries a heavy load of blood proteins. It is well known that the capillaries of the liver and intestine are more permeable to the blood proteins than are the capillaries in other parts of the body. It appears that the thoracic duct system is a special mechanism, the chief functions of which are the transportation of fat absorbed by the intestines and the rapid return of blood proteins to the blood (18).

The second system supplies the parietal peritoneum, it drains chiefly into the mediastinal lymph glands, and seems to have only circuitous communications with the thoracic duct.

Drainage of the thoracic duct, therefore, as a treatment for peritonitis is both inefficient and harmful. It removes little or no toxic material from the peritoneal cavity and depletes the blood of its proteins.

CONCLUSIONS

The abdominal veins act as a reservoir to regulate the supply of blood to the heart. Disturbances of this function may endanger life. The pressure in the intra-abdominal veins is always equal to the intra-abdominal pressure.

The circulation of the hollow, distensible organs of the abdomen may be impaired either by distention or by venous obstruction. The effects of distention are caused by an increase of pericapillary pressure; those of venous obstruction by an increase of intracapillary pressure. Arrest of the blood capillary circulation causes arrest of the lymph circulation, also.

Efforts so far made to treat peritonitis by preventing absorption from the peritoneum by way of lymph vessels have been based on erroneous ideas of the anatomy and the function of the abdominal lymphatics. The

prophylactic treatment of peritonitis by the production of aseptic inflammation of the peritoneum is well founded

TUBERCULOSIS OF THE KIDNEY

FRANK HINMAN, A B, M.D., F.A.C.S., San Francisco, California

THERE is nothing new to present upon renal tuberculosis. Methods of diagnosis and treatment have not changed in 20 years. The condition is surgical and nephrectomy is in order when the diagnosis is made. So I thought when the invitation to give this address arrived. After studying my own results with 181 patients cared for on this policy and after reviewing the literature to date, I still think so. This point of view, however, has been undermined by the suspicion, arising from recent experimental and pathological studies, that the disease is bilateral at onset, that this early bilateral tuberculosis may spontaneously heal on one or both sides and therefore that nephrectomy is not always in order as soon as the diagnosis is definite. In the opinion of those who hold this view the chance of cure by medical means should be given and, if a medical cure fails, nephrectomy should be postponed at least until the lesion is advanced far enough to have established some immunity.

The conflict of these ideas is detrimental to the victims of renal tuberculosis. Some patients will miss a chance of cure because the tuberculous kidney was not removed promptly, as the lesion will have spread to the bladder, to the opposite kidney, or to the genital tract. On the other hand, according to the opposing viewpoint, some patients who might have got well without it will suffer nephrectomy and among these will be some who, by this unnecessary and hurried operation, will have had tubercle bacilli let loose into their blood stream to form new lesions elsewhere or to stir old lesions into activity.

These differences of opinion are not irreconcilable. Nevertheless their variance is so apparent and, if not reconciled, so dangerous, that it is important to establish whatever accord there is in them. The truth in each may be brought out by a discussion of certain

practical points of diagnosis and treatment.

The diagnosis of tuberculosis of the kidney is established by finding pus and tubercle bacilli in the urine from that kidney. No other findings are needed. Pus without organisms of any kind arouses the suspicion of tuberculosis; tubercle bacilli alone have a meaning to be guessed at, but pus and organisms mean active tuberculosis.¹ Each examination leading to this conclusion, however, must have been precise and the findings true. Of this there must be no question. All possible sources of error must have been perceived and removed. The preliminary steps of examination which form the basis for special urological study are the history, the physical examination (particularly of the chest in all patients and, in males, of the external genitalia, the prostate, and seminal vesicles, in females, of the reproductive tract), the examination of the urine, tests of renal function, and x-ray exploration of the chest and urinary tract. These non-instrumental methods of examination should be complete in every detail before cystoscopic study is undertaken. On their completion urogenital tuberculosis usually is known to be present even though its extent and form are not known.

The use of the cystoscope and ureteral catheters now fulfills the need of a complete diagnosis. In no field of medicine can diagnosis be more exact nor the technical steps of achieving that diagnosis more precise. There would be no need for this if renal tuberculosis were a medical problem. Cystoscopy and ureteral catheterization, however, localize the lesions and make known their true extent and activity. By reason of the precision in accomplishing this, surgery of renal tuberculosis has been successful. Although you are not interested in the details of this examination, you should know that it results in wrong diagnoses and serious complications when carelessly per-

From the Department of Surgery, Division of Urology, University of California Medical School.

Presented before the Clinical Congress of the American College of Surgeons, Chicago, October 25-29, 1937.

¹It has been my custom to check this finding by a second examination and when pus and tubercle bacilli have been found twice in the urine from a kidney I have never hesitated to advise nephrectomy.

TABLE I—CLASSIFICATION OF RENAL TUBERCULOSIS

	epi/srectomy
Division I Unilateral	
1 Localized (no involvement of the bladder)	40
2 With involvement of the bladder	
a Mild	13
b Extensive	51
c With constriction of the ureter of the opposite kidney producing renal insufficiency	17
Total	81
3 With involvement of the genital tract	
a With involvement of epididymides	8
b With involvement of the prostate and seminal vesicles	2
c With involvement of epididymides, prostate, and seminal vesicles	13
Total	23
4 With extra urogenital tuberculosis	
a With involvement of lungs	17
b With involvement of bones	4
c With involvement of lungs and bones	4

formed. The study of the urine collected by catheter from each kidney leads the list in importance. When a ureter cannot be catheterized or a kidney forms no urine for study, the other tests then carry more weight. Among such tests, those of relative function are of value mainly as proof of the sufficiency of the opposite kidney to carry on after the diseased one is removed. Excretory urograms show both functional ability and structural changes but excretory urograms must be interpreted with caution and rarely should be accepted alone as enough for diagnosis. Retrograde pyelography of a kidney—a study of the urine from which has proved that kidney to be tuberculous, seems to me to be wholly unnecessary and not without danger. It can add nothing of value to diagnosis and because of the ease of pyelovenous backflow, it can flood the blood stream with tubercle bacilli. The urologist who requires a pyelogram showing the defects of filling caused by tuberculosis in order to complete his diagnosis of tuberculosis is not precise. The cystoscopic examination of a patient suspected of having tuberculosis of the kidney should not be carried through in the usual routine way, which usually consists of first, the collection of speci-

mens, (a) for microscopic study, (b) for culture and (c) for phthalein test of renal function—all of which are put aside and sent to the laboratory for study by a technician, and then pyelography (in the prone and upright positions). By this routine, the diagnosis is made from the pyelogram and then confirmed in a day or so by a report from the laboratory. It is my belief that a microscope and centrifuge available for use at the time of the cystoscopic examination are as necessary as the cystoscope and ureteral catheter for the precise diagnosis of renal tuberculosis. When pus and tubercle bacilli are found, pyelography is not needed and, because it is dangerous, should be condemned. Retrograde pyelography, however, is often valuable in determining the condition of an opposite non-tuberculous kidney which may be hydronephrotic, may contain stones or tumors or may be otherwise abnormal. It should be used only when the intravenous urograms are unsatisfactory and then only after all the known precautions against ureteropelvic reflux and soiling of the contents of the renal pelvis by catheter have been used. All of these precautions (a bladder well washed out and safeguarded against overdistention, each ureteral catheter filled with sterile water, the outside end securely plugged and the inside end surface lubricated for from 3 to 4 centimeters with sterile olive oil) should be used for every patient suspected by preliminary study of having tuberculosis. The foregoing points of diagnosis are clear and definite. Uncertainty arises when tubercle bacilli cannot be found or when there is a tubercle bacilluria without pus.

A sterile pyuria (pus in the urine without organisms detected by the ordinary methods of staining or cultivation) occurs not only in renal tuberculosis but also in the terminal stages of some pyogenic infections and in a disease rarely seen in this country but frequently reported abroad as an acute oblique pyuria. As a rule, these non-tuberculous forms of sterile pyuria can be recognized the first form by the past history of cystitis and pyelonephritis and the fact that a few irrigations of the bladder and renal pelvis clear it up. The second form is of unknown origin, affects young men mostly, rarely is found in women.

and starts acutely with bladder symptoms and even terminal hematuria without fever or any constitutional disturbance. The inflammation, as found in kidneys removed in error for tuberculosis, is confined to the mucosa of the pelvis. Recent cultural studies on Rosenow's bouillon by Schaffhauser¹ were positive for a non-hemolytic streptococcus which, when in-

oculated into dogs, reproduced the disease in them. Wildbolz² in Switzerland observed 21 patients with amicrobic pyuria. Six were cured by simple irrigations and the 15 who resisted any form of antiseptic treatment (given for years to some) got well promptly after one or two injections of neosalvarsan (0.15 gram). So specific is neosarsphenamine

that Wildbolz advised its routine use in differential diagnosis.

During this study of an aseptic pyuria, a diligent search for tubercle bacilli is being carried on continuously by the well known methods of microscopic examination, inoculation of guinea pigs, and bacteriologic cul-

ture. According to Pelz,¹ the microscopic search demonstrates tubercle bacilli in 72 per cent, the guinea pig test, in 94 per cent and the Loewenstein method of culture or some modification of it, in 98 per cent. Cultural methods have largely replaced the use of

257	Hematuria, frequency, nocturia, dysuria 2 yrs Cloudy urine 2 yrs Loss of weight 2 yrs			Fair	Advanced caseocavernous tuberculosis	Bladder ulcers persisted, in spite of intermittent fulguration, for 12 yrs Patient well 19 yrs later—no evidence of tuberculosis	X	O
258	Hematuria and cloudy urine 6 mos		X 4 mos	Fair	Caseocavernous tuberculosis	Urinary symptoms improved for 4 yrs, but became severe after that. Ulcers were fulgurated. Patient well except for frequency and nocturia 7 yrs later	O	
259	Hematuria and nocturia 2 yrs			Fair	Caseocavernous tuberculosis	Bladder ulcers were treated with irrigation and fulgurated 3 yrs later with good result. Patient developed active pulmonary lesion 1 yr later, which healed promptly Patient well 6 yrs later		
261	Frequency and dysuria 8 mos Hematuria 3 mos Loss of weight 3 mos	O	O	Fair	Advanced caseocavernous tuberculosis	Patient well 1 1/2 yrs later except for persistence of bladder symptoms	X	X Guinea pig

guinea pigs in which avian strains of tubercle bacilli are non-pathogenic. In my series of 300 patients, tubercle bacilli were found microscopically in 157. Of 62 patients tested by guinea pigs, 58 were positive. The cultural studies of the urine have been few and unsatisfactory. A diagnosis of renal tuberculosis was

made in 55 patients, and later confirmed by pathologic study, without tubercle bacilli ever having been found in the urine.

Let me discuss briefly the other condition a tubercle bacilluria without pus. It has been demonstrated indisputably, particularly since the advent of the newer cultural methods,

TABLE VI—DIVISION I UNILATERAL INVOLVEMENT

2c With involvement of the bladder and with constriction of the ureter of the opposite kidney producing renal insufficiency

Case No.	Symptoms	Dra n age of wound	Fistula Duration	Post operative course	Pathology	Remarks	Tubercles in ure from

Left epididymus moderate size. Stat and semi- nal vesicles adjusted	X	X
65	Frequency and nocturia 5 yrs		0	Poor	Caseocavernous tuberculosis	Bladder not improved in spite of intermittent fulguration. Left ureterovesicular junction tested 6 yrs later. Patient died of uremia 4 1/2 yrs after operation. Left semi- vaginal catheter placed in the ureterovesicular junction. Abscesses in kidney. No evidence of tuberculosis		
65a	Frequency dysuria and urgency 2 1/2 yrs. Hema- turia 2 yrs. Loss of weight 3 mos	Rubber dam	0	Fair	Caseocavernous tuberculosis	Right nephrectomy on 8-13-11. Left nephroctomy on 9-25-11. The kidney was found to be good at the time. In ph. stompy and its function improved rapidly. Left ureterovesicular transplant on 12-15-11. Patient well 3 yrs. later		

TABLE VI—DIVISION I UNILATERAL INVOLVEMENT—Continued
 2c With involvement of the bladder and with constriction of the ureter of the opposite kidney
 producing renal insufficiency

Case No	Symptoms	Drainage of wound	Fistula Duration	Post-operative course	Pathology	Remarks	Tubercles in urine from	
							Bladder	Kidney
107	Hematuria, frequency, nocturia		0	Good	Caseocavernous tuberculosis	Left kidney removed in 1917. Bladder ulcers persisted and capacity decreased to 20 c.cm. Right uretero-intestinal transplant 1-9-23. Patient improved. Right epididymectomy 6-19-23, this had to be followed by right orchidectomy because wound did not heal in 2 mos. Patient died at Central Emergency in February, 1924, of pneumonia.		
118	Frequency and dysuria 8 mos	Rubber tube	X 40 days	Poor	Left caseocavernous tuberculosis	Right nephrostomy and left epididymectomy 16 yrs later, bladder symptoms persisting	0	X
248	Frequency 17 yrs. Hematuria 10 yrs. Nocturia, dysuria, and urgency 4 yrs. Cloudy urine 10 yrs. Urine from both kidneys contained tubercles 4 yrs ago	Cigarette	0	Fair	Caseation at tips of calyces. Ulceration of pelvis	Right kidney has good function but urine from it shows pus cells and tubercles. Left kidney shows hydropnephrosis and poor function. Left nephrectomy. Epididymides, prostate, and seminal vesicles involved. Ulcers fulgurated intermittently for 1 yr. One year later a prostatic abscess broke into the urethra. Right nephrostomy 22 mos later. Kidney was grossly normal. Urine positive for tuberculosis. Patient died soon after with signs of uremia. No autopsy.	X	X
211	Pain in bladder 4 mos. Frequency and nocturia 6 mos. Loss of weight 1 yr	0	0	Fair	Caseocavernous tuberculosis of left kidney	Right kidney had good function. Urine from it contains tubercle bacilli. Left shows some hydropnephrosis and hydroureter. Right nephrostomy was done and kidney was grossly normal. Left nephrectomy was done 5 wks later.	X	X
232	Pain in right flank 4 yrs. Hematuria, frequency, nocturia, dysuria 6 yrs. Cloudy urine 1 yr. Pyuria 5 yrs ago	Cigarette	0	Good	Caseocavernous tuberculosis. Calculus. Caseation and fibrosis of ureter	Prompt improvement. Left hydro-nephrosis due to contraction and ulceration of bladder	X	0

that this condition exists frequently in all forms of extrarenal tuberculosis. A tubercle bacillema is just as frequent. That the kidney is not a bacterial filter has been firmly established also. Therefore, tubercle bacilli in the urine mean tuberculosis of the urogenital tract or of some structure in communication. Medlar started the controversy now under discussion when he demonstrated at autopsy bilateral tuberculous lesions of the kidneys in 23 patients in a series of 30 who died of pulmonary tuberculosis. None of these patients had had clinical evidence or signs of renal tuberculosis, such as pyuria. No doubt during life the urine of all 23 would have shown a tubercle bacilluria and the blood a bacillema. It has since been noted frequently, by various observers, that a bacilluria of this kind—that is

a bacilluria without pus—either with or without extrarenal tuberculosis, will disappear, and the inference that these early lesions have healed spontaneously is clear enough. To infer, however, because of these findings, that renal tuberculosis which clinically is so frequently unilateral, is actually bilateral at onset, is not so logical. I can see no reason why incipient or preclinical tuberculosis cannot involve one kidney and miss the other. The fact that staphylococcus nephritis is almost invariably unilateral has never been questioned. The invading staphylococci are carried by the blood from a furuncle or boil presumably in equal numbers to both kidneys, but only one suppurates. Why, then, in tubercle bacillema cannot one kidney be invaded and the other escape? Aside from this point

and the other possibility of bilateral invasion of staphylococci with spontaneous healing on one side afterward, the condition of tubercle bacilluria without pus is rare except with active extrarenal tuberculosis. There is always plenty of pus with clinical tuberculosis. Tubercle bacilli in the urine alone may be regarded as evidence of an incipient lesion. Such a lesion may heal with medical treatment. Nephrectomy would be in order only when the bacilluria persisted and increased

after years of observation. The viewpoint that renal tuberculosis is bilateral at onset and that it may heal spontaneously has little if any effect in actual practice on the treatment of renal tuberculosis. The majority of patients at the time of the clinical diagnosis have a unilateral lesion, which is the reason surgery is so successful. Of my 300 cases, 246 were unilateral and 44 bilateral. Ten patients had miliary tuberculosis. Furthermore no one has ever been able to prove that a renal lesion

177	Right low lumbar pain 2 yrs Frequency and dysuria 2 yrs Urgency 1 yr	Rubber tube	O	Fair	Advanced caseocavernous tuberculosis Tubercles in ureter	Supravaginal hysterectomy 1 mo before nephrectomy Examination of this specimen gave clue to diagnosis of tuberculosis Bladder showed many ulcers	O	O

which has once discharged pus and organisms into the urine has healed except by autonephrectomy

The point in diagnosis, therefore, is to differentiate between the preclinical and incipient forms of tuberculosis of the kidney—the treatment of which is mostly medical—and the

clinical form—the treatment of which is surgical. In addition, to make the diagnosis complete, all associated lesions must be recognized. To paraphrase Kipling. He knows not renal tuberculosis who only renal tuberculosis knows The whole extent of tuberculosis in the patient must be known. With a complete

Right kidney was enlarged and had tubercles in the pelvis. Left kidney was normal. Patient died of uremia. Both kidneys were tuberculous. On the tuberculous pelvis of the right kidney was a tuberculous abscess.	X	

TABLE IX.—DIVISION II BILATERAL INVOLVEMENT—Continued

Case No	Symptoms	Drainage of wound	Fistula	Post-operative course	Pathology	Remarks	Tubercles in urine from	
			Duration				Bladder	Kidney
133	Pain in lower back 4 mos Hematuria, frequency, nocturia, dysuria, and cloudy urine 4 mos.	Rubber tube	X 2 mos (still draining)	Poor	Tubercles in cortex	Urine from both kidneys showed tuberculosis. Left kidney function good, few pus cells seen in urine from it. Right kidney function very poor, urine from it loaded with pus cells. Right nephrectomy was done. Lung lesion became very active after surgery. Patient died of tuberculosis about 2 mos later.	X	X
148	Pain in left kidney region 4 days. Frequency, nocturia, dysuria 5 mos.	O	O	Poor	Tubercles in cortex	Patient well for 5 yrs. Returned because of hematuria. Ulcers then fulgurated intermittently 7 yrs. later ulcers looked like Künner's ulcer, urine negative for tuberculosis. At this time, following fulguration, urinary extravasation occurred and suprapubic cystostomy was done. 2 mos later perinephric abscess, which was drained. Died of uremia. Remaining kidney showed caseocavernous tuberculosis, lungs chronic tuberculosis.	O	O
9+	Pain in left flank 6 mos Hematuria 1½ yrs. Nocturia 6 mos.	Rubber tube	X 5 mos (still draining)	Poor	Caseocavernous tuberculosis of left kidney	Urine from both kidneys contains tubercle bacilli. Right kidney, good function, left kidney, very poor function. Left nephrectomy. Both epididymides nodular 5 mos later, patient improving.	X	X

diagnosis in this sense one can classify clinical tuberculosis of the kidney into the 5 groups as shown in Table I.

The foregoing subdivision of patients is important in settling the argument of medical versus surgical treatment. A spontaneous cure is most likely in patients in whom the lesion is confined to one kidney. At the same time, removal of this kidney before the lesion has spread elsewhere might cure all of these patients, or at least more than are cured when associated lesions are present. This group (i.e., patients with localized unilateral involvement) is most favorable therefore for both medicine and surgery, and the answer to the question, "which is preferable?" should be found in a comparison of end-results. There has not been time to complete my follow-up records. As it stands, 66 patients had localized renal lesions (Table I) and unilateral nephrectomy was done promptly in 40. All of these 40 patients were alive and none of them showed any evidence of tuberculosis when last examined. Perhaps many of the 32 patients in the group not operated on have had their kidneys removed elsewhere, and it is possible that only a few of those who did not have such surgery, have received adequate medical care.

It would be instructive to know what happened to those who had proper medical care. Nevertheless we do know that in this group of patients who had no involvement of the bladder or elsewhere, nephrectomy was time-saving, safe, and entirely satisfactory. No flare-up or spread of tuberculosis occurred after nephrectomy. In comparing the duration of symptoms in the four subdivisions of the unilateral group, it is seen that the diagnosis in those patients who had tuberculosis limited to one kidney, and clean bladders, was made no earlier than in those who also had active tuberculosis of the bladder or genital tract, phthisis or tuberculous osteomyelitis, alone or in some combination (Table II). Barely 40 per cent of patients with localized renal tuberculosis had had symptoms less than 1 year and only 3 for less than 3 months, whereas in the 129 with vesical, genital, and other lesions, symptoms had been present for less than 3 months in 15 and for less than 1 year in 59. In other words, those patients in whom the tuberculosis was localized in one kidney seem to have had as much chance to develop bodily resistance and a general immunity to the infection as the others. The fact that the infection was confined to one kidney in these pa-

TABLE IX—DIVISION II BILATERAL INVOLVEMENT

Case No	Symptoms	Drainage of wound	Fistula Duration	Post operative course	Pathology	Remarks	Tuberculous mass from	
							Bladder	Kidney
164	Pain in lumbar region 5 yrs. Frequency and nocturia 7 yr. Draining sinus in neck 3 yrs.	Rubber tube	✓ 4 mos.	Poor	Spectrum obtained at time of left nephrectomy showed caseocavernous tuberculosis	Right kidney has no function. Left hydronephrosis with several constrictions in ureter. Left nephrostomy was done and kidney function improved. Left's renal calicular point involved. Right epididymus nodular, it drained 20 yrs. ago and gradually closed. that portion of the ureter which was not removed. Nine of 38 patients on whom Beer¹ did extensive ureteronephrectomies developed sinuses in the lumbar wound and only 3 of the 38 had a sinus form in the rectus incision through which the ureter had been enucleated; all 3 were explainable on the basis of contamination of the wound at the time of ureterectomy. An attempt to remove the whole ureter is unnecessary, and the additional surgery required for it may be detrimental.

CONCLUSIONS

The conception that renal tuberculosis is bilateral at onset, that in the majority one side heals spontaneously leaving a unilateral lesion and that occasionally both sides may so heal, should have no effect whatsoever upon the management of clinical renal tuberculosis.

This conception, however, necessitates more than ever the differentiation of preclinical and other forms of tuberculosis of the kidney—such as miliary tuberculosis—from the clinical forms of the disease.

The finding of pus and tubercle bacilli in the urine points definitely to the clinical form of renal tuberculosis. The diagnosis is not complete, however, until all possible associated lesions have been searched for and recognized.

¹Ann Surg, 1936, 104 748-751

The urological examination must be precise with every precaution against spreading the infection. For this reason, the routine use of retrograde pyelography is condemned.

The clinical form is unilateral in over 85 per cent of patients when first diagnosed, but in relatively few of these has it remained confined to the kidney. Involvement of the bladder is common and genital and extra-urogenital lesions occur frequently in association with the renal lesion.

World-wide experience demonstrates the superiority of nephrectomy in the treatment of unilateral tuberculosis of the kidney. When tuberculosis is localized in the kidney and the patient has been properly prepared, nephrectomy is almost 100 per cent curative. When associated lesions exist in the bladder, seminal tract or elsewhere, nephrectomy is still from 60 to 70 per cent curative.

Nephrectomy is rarely an emergency procedure and should be performed only after a complete study and careful preparation.

An attempt should be made to perform a clean extracapsular enucleation by the extra-peritoneal lumbar route during which the kidney should be squeezed and manipulated as little as possible. Clamping of the pedicle should be the first objective. As much of the ureter as is accessible should be removed but a complete ureterectomy is unnecessary.

tients may indicate even a greater immunity. Furthermore, comparison of the condition of the kidneys which have been removed shows that the lesions in the kidneys of the patients with localized tuberculosis are as a rule as far advanced as those in the kidneys of patients with generalized tuberculosis.

The point I wish to emphasize, one often mentioned by urologists but never sufficiently recognized generally, is that the removal of a kidney in which tuberculosis is primary (i.e. there is no active tuberculosis elsewhere) before the infection has spread to the bladder is almost 100 per cent curative, whereas its removal after the bladder has become involved is little more than 60 per cent curative. I am speaking of clinical tuberculosis, the diagnosis of which is based on the finding of pus and tubercle bacilli in the urine and in which the pathologist will usually find a caseocavernous lesion.¹ The importance of not confusing this condition with preclinical tuberculosis of the kidney with which an active tuberculosis elsewhere is usually associated, is obvious.

The superiority of surgery in the treatment of clinical renal tuberculosis is found in the published records for the past 30 years of clinics throughout the world. For example, Hryntschak² of Vienna reported recently that 60 per cent of all his patients were well and free of tuberculosis 10 years after nephrectomy, whereas only 24 per cent of those not operated on were alive 12 years later and every one of them was still suffering severely with tuberculosis. This year Gile³ analyzed the known results in 84 of 93 nephrectomies in Squier's clinic, New York (there was no follow up record in 9). Fifty two of the 84 patients (31 of whom had extra urinary tuberculosis) are living and free of tuberculosis. Such statistics could be multiplied indefinitely.

The surgical risk of nephrectomy for renal tuberculosis is small, in my series there were 4 deaths from operation in 181 nephrectomies, 1 from embolism, 1 from shock, and 2 from uremia, of the latter, 1 patient had polycystic kidneys and the other had bilateral tuberculosis. Nephrectomy is rarely, if ever an

emergency procedure. The question of pre-operative preparation, its character and duration should be considered separately for each patient and should be answered according to his physical and economic situation. Sanatorial treatment is beyond the reach of some unnecessary for others. In any event, if adopted, the patient should understand that it is pre-operative. Any patient with acute symptoms, particularly fever, should have preparation by rest, fresh air, and over feeding even if only for 10 days or 2 weeks, and those patients in the group with primary tuberculosis limited to one kidney are no exception. It is a mistake, however, to attempt a cure of these patients by medical means just because the tuberculosis is limited. The risk of causing military tuberculosis at the time of operation is no greater in this group than in the others if the patient is prepared and the operation is not performed until after the very acute symptoms have subsided.

The risk that the remaining kidney will become tuberculous after nephrectomy is also small. Wildbolz, in an experience with over 600 nephrectomies, found the incidence to be less than 1 in 100 only 5 developing infection in the second kidney later. This rather nullifies the idea that renal tuberculosis is bilateral at onset. In a group of 17 patients (Table I, Division I, subdivision 2 subgroup c) with involvement of the bladder so extensive as to impair the function of the remaining kidney, subsequent examination of the kidney at the time of nephrostomy in 6 and at autopsy in 2 showed no tuberculosis. The incidence of a persistent sinus after nephrectomy, however, remains high. A sinus persisted longer than 2 months in 26 of 95 patients in whom a drain was inserted and a sinus developed in 4 of 60 in whom closure was done without drainage (Table II). As a rule an extracapsular encapsulation of the kidney was attempted and usually when the capsule had been adherent or pus had been spilled into the wound, a drain was inserted. The few cases of formation of a sinus after tight closure therefore cannot be used as an argument in its favor. It is my impression that a sinus usually persists or forms because of tuberculosis of perirenal tissues and rarely because of tuberculosis of

increased in acute pancreatitis. The increase in diastase is frequently demonstrable within 6 to 8 hours after onset of the acute disease and diminishes or disappears after 2 or 3 days; the augmentation of the serum lipase is produced only 2 or 3 days after onset but continues for quite some time, 1 to 4 weeks, at an abnormal level. These tests constitute valuable corroborative aids when facilities for their performance are available.

Sex and age. Of the 30 cases observed by us, 14 occurred in men and 16 in women. The average age of the patients was 40.7 years, 1 being in the second, 4 in the third, 7 in the fourth, 7 in the fifth, 9 in the sixth, 1 in the seventh and 1 in the eighth decades.

Previous history. Twenty-two gave a history of gall-bladder disease varying in length from 3 months to 20 years with an average duration of 3 years and 5 months, 14 gave a history of previous colics and 8 of colic immediately preceding onset of pancreatitis. Two had had cholecystostomies with removal of stones, one 6 years and one 8 months, and 3 had had drainage for acute pancreatitis, one 4 years, one 4 months, and one 8 months before present illness.

Duration of symptoms referable to pancreatic involvement. These had existed in 1 for 1, in 5 for 2, in 8 for 3, in 3 for 4, in 4 for 5, in 5 for 7, in 1 for 6, in 1 for 10, in 1 for 14 and in 1 for 16 days. In 18 the symptoms developed in from 1 to 4 weeks following gall-bladder colic, in 14 the initial pain represented the only colic.

Pain. The pain was noted as severe, accompanied with nausea and vomiting in 21, being of the hyperacute type in 9; in the remaining 9 while the onset was similar it was of milder degree. The pain was located in the epigastrium and right hypochondrium in 14, in the left hypochondrium in 5, and extended across both upper quadrants in 11. Cyanosis was noted in 2 and jaundice in 3. No patient was seen in profound shock, doubtless due to the period of time elapsing between onset of illness and period of observation. The pulse in 9 was below 100 and in 21 ranged from 100 to 140. The temperatures varied from 99 to 104 degrees. The leucocyte count in 9 was below 10,000 and in 21 ranged from 10,000 to 44,200.

Urine. The urine in all showed the presence of albumen; none showed the presence of sugar. Bile was present in 8, casts in 6, blood in 10, and pus in 13.

Mass. In 17 no mass was detected, while in the 13 remaining an enlargement was distinctly palpable, being located in the right upper quadrant in 7, in the left upper quadrant in 2, and in 4 it lay transversely across the epigastrium.

Pre-operative diagnosis. The diagnosis in 14 was acute cholecystitis, in 12 acute pancreatitis, in 2 acute appendicitis, in 1 intestinal obstruction, and in one "acute abdomen."

Morbid anatomy. Free fluid was found in the greater peritoneal cavity in 8, being bile-tinged in 3; hemorrhagic fluid exudate was present in the lesser peritoneal cavity in 15, varying in amount from a few to 2,600 cubic centimeters. Demonstrable fat necrosis existed in 15. Recognizable disease was present in the gall bladder in 24, calculi in the gall bladder in 18 and in the common duct in 2. The gross lesions of the pancreas presented as acute edema in 9, as acute necrosis in 10, as hemorrhagic pancreatitis in 9, and as pancreatic abscess in 2, there being a wide variety of findings apparently depending upon the stages at which the patients came to operation. In the cases of acute pancreatic edema the swelling of the organ increased its size to two or three times the normal, the consistencies varying from soft to almost stony hardness. Edema, differing in degree, was noted in the omental, mesenteric, and adjacent retroperitoneal tissues, in one instance extending throughout the mesentery of the ascending and transverse colon; the edema in the tissues about the common duct in some of the cases produced marked distortion of anatomical relations.

The primary lesion in pancreatic necrosis starts in the lobule and may be limited to one part of the organ or may involve a considerable portion of it. Sloughs containing devitalized pancreatic tissue may be removed at operation or may be extruded later from the drainage tract. In the cases of hemorrhagic pancreatitis the extent of the hemorrhage depends upon the size and number of vessels

ACUTE PANCREATITIS

IRVIN ABELL, M A, M D, F A C S, Louisville Kentucky

IN an experience embracing approximately 2,000 operations on the biliary tract, the writer has encountered 30 cases of acute pancreatitis. The term "acute pancreatitis" as here employed covers four clinical pictures—acute pancreatic edema, acute pancreatic necrosis, acute hemorrhagic pancreatitis, and pancreatic abscess—which are not separate clinical entities but are believed to represent different stages of the same process. It is worthy of note that the entire modern interpretation of diseases of the pancreas is based upon the fact that pancreatic lesions are looked upon as more or less secondary affaits, the idea being that the primary cause outside the pancreas should be sought first in making the diagnosis. The rapid destruction of pancreatic tissue is due to the activation of trypsinogen within the gland itself, normally this is done by the enterokinase in the duodenum. The commonly accepted explanation for the activation of the trypsinogen within the pancreas is that a retrograde infection has taken place from the passage of infected bile or of duodenal contents through the ducts of Wirsung and Santorini, and further minute hemorrhages and bacterial toxins resulting from a pancreatic lymphangitis may be activating agents. Biliary tract infection constitutes by far the most frequently found 'primary' disease found in all forms of pancreatitis. In 2 of our cases the acute pancreatitis was associated with a penetrating ulcer of the duodenum the inflammation in the pancreas could well have been an extension through contiguous tissue. We have repeatedly observed that a more or less localized chronic pancreatitis due to penetrating duodenal ulcer readily affords a pathological basis for the provocation of an acute process. Inflammatory obstruction of the pancreatic duct system occurs with rupture of some of the ductules and consequent activation of trypsinogen into trypsin. Rich has shown that

metaplasia of the duct epithelium with resultant obstruction and localized dilatation of the terminal ductules is a not uncommon finding in the pancreas and advances this as a further explanation of the cause of acute pancreatitis. In the histological examination of the pancreases of 150 unselected cases removed from individuals dying from various causes other than disease of the pancreas metaplasia of the pancreatic duct epithelium was found in 28 or 18.6 per cent. Localized dilatation of the terminal ductules was also found in the 28 cases and in 17 additional cases in which the cause of the obstruction could not be discovered in the section of the pancreas available for study. The result of rupture of the acini dependent upon such obstruction will depend upon the action of the trypsin on the vessels with which it comes in contact, and will vary from resolving lesions producing scar formation to some variety of clinical acute pancreatitis.

There are no pathognomonic clinical symptoms the most important of which is pain which, with nausea vomiting and collapse will vary with the acuteness of the pancreatic disturbance and the resistance of the patient. Previous history of gall bladder disease, pain radiating from the right costal margin across the upper abdomen, tenderness following the course of the pancreas pain and tenderness to the left of the upper midline and the detection of a mass in the pancreatic area, are beacon lights when elicited. The phenomenon of general intoxication, like the secondary symptoms proceeding from the liver and the kidneys (icterus urobilinuria and hematuria) does not have a diagnostic value either large or direct but these secondary symptoms are of supreme importance in the matter of prognosis. The liberation of the ferments in the pancreatic parenchyma leads to an increase in the amount of diastase in blood and urine, the urine normally contains 10 to 20 units of diastase and the serum value remains commonly at about 170, both being greatly

increased in acute pancreatitis. The increase in diastase is frequently demonstrable within 6 to 8 hours after onset of the acute disease and diminishes or disappears after 2 or 3 days; the augmentation of the serum lipase is produced only 2 or 3 days after onset but continues for quite some time, 1 to 4 weeks, at an abnormal level. These tests constitute valuable corroborative aids when facilities for their performance are available.

Sex and age Of the 30 cases observed by us, 14 occurred in men and 16 in women. The average age of the patients was 40.7 years, 1 being in the second, 4 in the third, 7 in the fourth, 7 in the fifth, 9 in the sixth, 1 in the seventh and 1 in the eighth decades.

Mass. In 17 no mass was detected, while in the 13 remaining an enlargement was distinctly palpable, being located in the right upper quadrant in 7, in the left upper quadrant in 2, and in 4 it lay transversely across the epigastrium.

Pre-operative diagnosis. The diagnosis in 14 was acute cholecystitis, in 12 acute pancreatitis, in 2 acute appendicitis, in 1 intestinal obstruction, and in one "acute abdomen"

Morbid anatomy Free fluid was found in the greater peritoneal cavity in 8, being bile-tinged in 3; hemorrhagic fluid exudate was present in the lesser peritoneal cavity in 15, varying in amount from a few to 2,600 cubic centimeters. Demonstrable fat necrosis existed in 15. Recognizable disease was present in the gall bladder in 24, calculi in the gall bladder in 18 and in the common duct in 2. The gross lesions of the pancreas presented as acute edema in 9, as acute necrosis in 10, as hemorrhagic pancreatitis in 9, and as pancreatic abscess in 2, there being a wide variety of findings apparently depending upon the stages at which the patients came to operation. In the cases of acute pancreatic edema the swelling of the organ increased its size to two or three times the normal, the consistencies varying from soft to almost stony hardness. Edema, differing in degree, was noted in the omental, mesenteric, and adjacent retroperitoneal tissues, in one instance extending throughout the mesentery of the ascending and transverse colon; the edema in the tissues about the common duct in some of the cases produced marked distortion of anatomical relations.

The primary lesion in pancreatic necrosis starts in the lobule and may be limited to one part of the organ or may involve a considerable portion of it. Sloughs containing devitalized pancreatic tissue may be removed at operation or may be extruded later from the drainage tract. In the cases of hemorrhagic pancreatitis the extent of the hemorrhage depends upon the size and number of vessels

eroded, it may be limited to comparatively small areas or may be extensive as exemplified in 2 of our cases. In one the entire pancreas was embedded in a large clot, in the other the hemorrhagic extravasation involved the lesser peritoneal cavity, the retroperitoneal tissues, the mesentery of both transverse and ascending portions of the colon as far as the cecum, spreading out laterally from the latter as far as the midline internally and as far as the reflexion of the posterior parietal peritoneum externally. It seems to me that the term acute hemorrhagic pancreatitis should be discarded, if one wishes to emphasize the clinical feature of bleeding, the term acute pancreatic necrosis with hemorrhage more accurately describes the underlying pathology. Of the 2 abscesses, 1 was located in the pancreatic tissue, the mass projecting into the lesser peritoneal cavity and when opened yielded 6 ounces of pus showing a pure culture of colon bacillus, the other originating in pancreatic tissue involved as well the lesser cavity.

Operations involving pancreas—

Gauze tamponade with rubber tube (Penrose)	15
Additional operation on bile tract	
Cholecystostomy	13
Cholecystectomy	1
Drainage lesser peritoneal cavity alone	3
Drainage lesser cavity with cholecystostomy and choledochostomy	1
Evacuation of abscess with cholecystostomy	2
Operations not involving pancreas—	
Cholecystostomy alone	5
Cholecystectomy and duodenocholestomy alone	2
Cholecystoduodenostomy alone	2
Duodenojejunostomy alone	1

In our earlier experience from 1917 to 1925, an effort was made in 6 cases to introduce the drainage material directly into pancreatic tissue, in 2 instances going as far as to incise hemorrhagic areas for this purpose but 1 of these patients died, an outcome which in the light of our present day belief may be regarded as fortuitous. The drainage of the lesser peritoneal cavity alone in 3 patients was employed for the evacuation of rather large hemorrhagic exudates in one amounting to 2600 cubic centimeters. The cholecystoduodenostomy was employed in a patient who first came under observation with marked jaundice and profound sepsis, at operation no stones were found in gall bladder pancreatic enlargement and fat necrosis were present

and the gastrohepatic omentum covering common duct was greatly thickened and edematous. A cholecystostomy alone was done and some weeks later, after subsidence of the jaundice and sepsis, the abdomen was reopened, a single non faceted stone being removed from the terminal portion of the common duct. Following this the patient remained symptom free for 8 months when she developed an acute pancreatitis, the pancreatic mass being palpable through a thick abdominal wall. At operation the organ presented an acute swelling being three to four times its normal size while the parapancreatic tissues showed a greenish hued edema. After the gall bladder and duodenum were freed of adhesions an anastomosis was made between them and the patient recovered.

The duodenojejunostomy was done in a patient 22 years of age who came to us with a history of repeated colics, the last or present one of which was severe and accompanied by fever and jaundice. Operation revealed a huge duodenum due to obstruction at the duodenojejunal junction, the presence of a perforating duodenal ulcer into the head of the pancreas, pancreatic enlargement, and fat necrosis. The duodenum was opened through the transverse mesocolon and cleansed of an accumulation of seeds, beans, corn, and 3 one cent pieces, after which it was anastomosed with the jejunum followed by recovery of patient. The obstruction at the duodenojejunal junction was evidently congenital in origin, the mother stating that the three coins had been swallowed at the age of 6 years.

Mortality. There were in the series, 9 deaths a mortality of 30 per cent. Five occurred in the acute pancreatic necrosis and 4 in the acute hemorrhagic pancreatic groups with none in the acute pancreatic edema and pancreatic abscess groups. Three of the acute necrosis cases had pancreatic drainage alone, and patients died on the eighth, thirtieth, eighth and one hundred and eleventh post operative days, autopsy in the 2 latter showed extensive retroperitoneal necrosis and suppuration. Of the 2 remaining acute necrosis cases 1 patient had pancreatic drainage and cholecystostomy and died on the third day and 1 had cholecystectomy and chole-

docholestomy alone, the diagnosis of the pancreatic lesion at time of operation being edema, and death occurred on the ninth postoperative day, autopsy showing extensive pancreatic necrosis. Of the acute hemorrhagic pancreatitis group, 1 had cholecystostomy with evacuation of hemorrhagic fluid from and drainage of the lesser peritoneal cavity, death following 4 hours after operation. Two, 1 with cholecystostomy alone and 1 with cholecystectomy and choledochostomy, presented marked enlargement of the pancreas at time of operation thought by me to be edema, 1 died on the sixth and 1 on the ninth day after operation, the autopsy showing hemorrhagic pancreatitis in both. The fourth patient in this group presented an extensive hemorrhagic pancreatitis, the lesser peritoneal cavity being distended with hemorrhagic exudate and blood clots and the gall bladder and common duct buried from view in dense adhesions. Evacuation and drainage of the lesser cavity were done without drainage of the biliary tract. Convalescence was stormy but finally reached a stage at which patient was able to be up, when on the forty-eighth postoperative day there was a recurrence of pain, free hemorrhage from the drainage tract, hematemesis, and melena, with death on the fifty-fourth postoperative day.

Acute pancreatitis until within recent years has been universally regarded as an indication for immediate operation, the accepted indications being to relieve tension, to stop hemorrhage, to prevent leakage, and to afford drainage. In the belief that operative procedure will neither lessen nor control the formation of trypsin nor prevent its further destructive action in the pancreas, there are many at the present time who contend that operation is best deferred until the acute pancreatic symptoms subside. The claim is made that by so doing opportunity is given for localization of the pancreatic disturbance while early operation tends to break down protective barriers and to increase the dangers of necrosis and hemorrhage from trauma to the diseased organ. While in the series herewith reported there has been no delay in operating upon patients after admission to the hospital other than that occasioned by res-

toration of fluid balance and rehabilitation by transfusions, an analysis of it finds much to support the advocates of delayed operation. We have not hesitated to employ glucose solution intravenously although theoretically contra-indicated by the elevation of the blood sugar thus increasing the flow of pancreatic enzymes. The rapid depletion of liver glycogen dependent upon the absence of food and the presence of vomiting, together with the frequency of liver damage shown at post-mortem, would indicate its use, the objection to which can be obviated by the simultaneous administration of insulin. There were no deaths in the 2 cases of abscess and 9 of acute edema, but it is to be noted that in 3 cases classified at operation as acute edema in which the surgical procedure was limited to the correction of the associated pathological condition in the bile tract, death followed on the sixth, eighth, and ninth postoperative days, autopsy showing in each acute pancreatic necrosis. The interpretation of the pancreatic pathology may have been erroneous; the operative trauma may have activated the pancreatic disease or what is more probably correct, the pancreatic edema was but the primary state of the necrosis. It has been stated that edema of the pancreas does not necessarily make the transition to necrosis and hemorrhage, an observation borne out by the 9 recoveries in this group; it has been further stated that edema may very well be looked upon as an independent malady with good prognosis for the most part and with indications for operation decidedly different from those of necrosis, hemorrhage, and abscess. That the indicated operative procedures are different most surgeons will agree, but there will be found wide dissent upon the hypothesis that edema is a separate entity. The performance of the operations with relation to the onset of symptoms relating to the pancreas was as follows: 6 on the second day with 4 recoveries and 2 deaths; 8 on the third day with 3 recoveries and 5 deaths; 3 on the fourth day with 2 recoveries and 1 death; 4 on the fifth day with 3 recoveries and 1 death; in the remaining 9 done from the sixth to the sixteenth day there were no deaths. The entire mortality followed operations done from the

second to the fifth day, 7 of the 9 ensuing from those done on the second and third day, while no fatality was noted in operations after the sixth day. These results apparently indicate the comparative safety of the delayed operation, but I cannot escape the conviction that some of the recoveries would have been converted into fatalities by delay. The operative record of one such recovery will indicate the pathological basis for such belief.

When the peritoneum is opened bile tinged fluid escapes. Visible omental and mesenteric fat shows the presence of multiple areas of fat necrosis. Gall bladder tightly distended and covered by adherent omentum and colon. Gastrohepatic omentum shows the presence of gangrenous areas and upon perforation a quantity of hemorrhagic fluid escapes from the lesser cavity. Penrose drain is placed down to and above the head of the pancreas. Gastrocolic omentum is opened and Penrose drain placed along lower border of pancreas. Examination of the mesocolon at the hepatic flexure shows that the pancreatic fluids have caused a rather extensive retroperitoneal necrosis; this spreads laterally from the mesocolon reaching the lateral abdominal wall to the outer side and extending well toward the vertebral column on the inner side. Penrose drains are placed in the slit mesocolon and in the gutter between the ascending colon and the abdominal wall. Gall bladder is opened, stones evacuated and drainage made with rubber tube all drains being brought out middle third of incision.

The period of time elapsing between operation and death was 4 hours in 1, 3 days in 1, 6 days in 1, 8 days in 1, 9 days in 2, 38 days in 1, 54 in 1 and 111 in 1. In the 3 patients living longer than 9 days pancreaticasthenia was noted characterized by weakness, nausea and anorexia, death occurring in one with recurrence of bleeding from the drainage and gastro intestinal tracts indicating a further diffusion of trypsin, and in the 2 remaining from exhaustion, autopsy showing extensive pancreatic and retroperitoneal destruction. With the exception of the 1 patient dying of shock all died of tryptic digestion of the pancreas. As this process is a chemical and not an inflammatory one the proponents of the delayed operation believe that the use of gauze tamponade and drainage does not favorably influence the reparative process in pancreas. In 8 of our 9 cases this assumption is borne out. Three patients suffered recurrent attacks of acute pancreatitis at 4 months, 8 months

and 4 years, respectively, in all 3 of which gall stones were removed and the gall bladder drained at the first operation. Assuming the correctness of the belief that biliary tract disease is the predominant etiological factor, this experience would indicate the advisability of cholecystectomy in patients recovering from attacks of acute pancreatitis as a prophylactic measure against recurrence. Since such a procedure can rarely be safely done in the presence of an acute attack, it becomes an added argument for the deferred operation. The observation of areas of fat necrosis in interval operations upon patients giving histories of severe biliary tract disease is not such an uncommon one and affords conclusive proof of spontaneous recovery from acute pancreatitis.

The difficulty in making a correct pre-operative diagnosis adds no little to one's perplexity in deciding for or against deferred operation and in evaluating the results of the proponents of the latter. The gravity of the lesion is such that deaths will of necessity follow both plans of treatment. If one elects the deferred plan, unless he is willing to make exploratory operations in doubtful cases or is possessed of unusual diagnostic acumen the mortality will be but increased by high obstructions, ulcer perforations, and gangrenous cholecystitis. The correct pre-operative diagnosis was made in but 12, or 40 per cent of our series, the error in 14, or 47 per cent lay in thinking the lesion to be acute cholecystitis. It would be of interest to know in how many instances of acute surgical conditions of the abdomen a diagnosis of acute pancreatitis had been made and at operation pancreatitis was not found, unfortunately no such data are at hand.

CONCLUSIONS

1. Acute pancreatitis comprises 3 clinical groups which are but different stages of the same process, acute pancreatic edema, acute pancreatic necrosis, and pancreatic abscess.
2. The deferred operation offers definite advantages in selected cases, a correct diagnosis being essential to its employment.
3. Patients presenting jaundice and with palpable masses due to distention of the lesser

peritoneal cavity, with manifest enlargement of the gall bladder, or with evidence of spreading peritonitis, are best treated by early operation.

4 Operative attack on the pancreatic tissue is not justified; drains, gauze, or Penrose drain should be placed down to, but not in, pancreatic tissue

5. The utmost gentleness should be exercised in handling the pancreas and para-

pancreatic tissue; pressure from retractors is to be studiously avoided.

6. Bile-tract disease, the predominant etiological factor in the light of present knowledge, should receive such surgical attention as time of operation and the local pathological condition permits. If early operation is done, drainage at least should be instituted. In delayed operations a complete toilet of the bile tract is desirable

THE PRESENT STATUS OF THE OPERATIVE TREATMENT OF FRACTURES

WILLIAM O'NEILL SHERMAN, M.D., F.A.C.S., Pittsburgh, Pennsylvania

THE pioneers of the operative treatment of acute fractures as practiced today are Lambotte of Antwerp and Sir Arbuthnot Lane of London. To these courageous surgeons, who have made such substantial contributions to the surgical armamentarium and technique, we owe a great debt of gratitude

A recent visitor to our clinic from Australia, who had spent 18 months visiting the various clinics of Great Britain, Europe, and the United States, asserted he was very much confused and in great doubt as to what procedures or practices were best because of the many and divergent methods employed, as well as the claims made for each of them

The introduction of x-ray films as evidence in Court, with interpretations by the laity, now constitutes a legal threat to force a more accurate anatomical replacement of fractured bones. The patient is frequently under the impression that the "Doctor has set the fracture" only to realize, months or years later, that it had not been reduced. It is, therefore, advisable to show the x-ray films to the patient and to explain the conditions, indications, etc., if operative procedure is necessary. When the patient is confronted with the fact

that he is likely to go through life with a limp, loss of function, or similar disability, he will readily consent to submit to a reasonable and safe recommendation. A surgeon would not permit a fracture to remain uncorrected either in himself or members of his family. Why should not the same consideration be extended to his patients?

For the past 30 years severe criticism has been leveled at those who have used steel bone plates, screws, nails, etc. Many of the leading critics in personal interviews have admitted to me that they never had had any experience whatsoever with steel plates, screws, or nails in the treatment of acute fractures and that their opinion was based entirely on the poor end-results which they have seen in cases in which the operation was imperfectly or poorly done. In the medical schools certain of the professors, when discussing the operative treatment of fractures, stated, "We merely mention steel plates, screws, and nails in order to condemn or decry their use."

In July, 1929, the author attended a meeting of British and American bone and joint surgeons in London. One morning of the program was devoted to the discussion of the treatment of intracapsular fractures of the hip joint. Royal Whitman made a valiant

stand for the anatomical reduction and physiological treatment by the abduction method, plaster, and rest. A group of 14 cases was presented in which the Thomas splint had been used and was advocated as the method of treatment with traction and immobilization. There was a questionable reduction in all of the cases and the end functional results were anything but satisfactory. There was no criticism made, however, of the use of the Thomas splint. Philip Wilson made a brief preliminary verbal report of 23 cases in which patients had been treated by the operative method by Smith Petersen. Mere mention of the operative treatment was severely condemned notwithstanding the fact that those making the condemnation had little or no knowledge of the operative technique. Much credit is due Smith Petersen for his contribution to this subject. The technique now has been refined so that with the assistance of the x-ray as a guide, only an incision over the trochanter is necessary to insert steel fixation in the form of nails or screws. The results reported by Smith Petersen, Watson Jones, Sven Johansson, Brewster, Moore and Cubbins and his group, are very encouraging and while it is too early to evaluate the end functional results there is ample justification for this technique at the present time in the hands of those trained and competent.

The high mortality and large percentage of non unions as a result of the abduction method make it imperative that something be done to shorten the convalescent period and improve end functional results; hence it is obvious that such operations should be done only by those exceptionally well trained and equipped.

It is certainly desirable to make these patients ambulatory in from 5 days to 2 weeks as against the patient remaining in a "coffin of plaster of paris" for a period of 3 to 5 months.

Since the World War there has been "mass production" of bone and joint specialists, many of whom lack general surgical training. A surgeon who requires 3 hours to do an operation that should be done in 45 minutes should not attempt it.

VANADIUM STEEL BONE PLATES AND SCREWS

In 1909, following Sir Arbuthnot Lane's advocacy in America of the use of steel plates and screws, the author adopted this technique when operation was indicated and in 1911 he reported 72 operative cases. It was soon found that the screws were too soft and the plates too hard, with the result that the screws pulled out and the plates broke. This led to the redesigning and patenting of vanadium plates and screws in 1911, with the idea of securing plates having maximum strength with a minimum amount of foreign material. If the plates and screws are made according to specifications they will not break, but quantity production during the World War resulted in the market being flooded with plates and screws which had never been inspected either from a physical or metallurgical standpoint. The havoc produced by the breaking of these plates and by the pulling out of these screws, brought a storm of protest to the American College of Surgeons from surgeons throughout the country. The author presented his patents to the College and the Fracture Committee took up the matter with the United States Bureau of Standards. After a thorough joint investigation, they adopted and approved as standard the same designs of the plates and screws as advocated in 1909, as well as the metallurgical specifications as set forth in the patent.

The undesirability of beef bone, ivory, gold, silver, and metals containing copper, chromium and nickel after the great claims made for them, is a matter of common knowledge.

"Cat and dog" experimenters have strenuously objected to the use of steel in the fixation of fractures quite unmindful of the fact that as a result of the high explosives used in the World War, millions of individuals carry iron and steel about in their bodies without localizing or irritating symptoms. There are also many thousands of individuals who have been operated upon during the past 30 to 40 years in whom the plates have remained *in situ* without deleterious effects. We take strong exception to the teaching that plates and screws should be removed unless there are specific indications for their removal.

If the proper technique is followed in applying plates, 95 per cent will remain permanently in simple fractures without any necessity for removal, whereas 48 per cent *are* removed in compound fractures. The results of animal experiments in which steel plates and screws have been used and condemned, are not of great value because of the difficulty in carrying out the meticulous, non-touch technique so necessary.

Non-ferrous substances are being advocated but they are not comparable to the steel alloys in their physical characteristics. The objection to them is, they are too bulky and hard and, therefore, liable to fracture. The objection to stainless steel is that it contains chromium and is rather difficult to temper. Ductility, and not extreme hardness, is the quality most desired.

Electrolysis is not a factor when plates and screws are made of the same steel. In cases in which plates have been removed, the staining of periosteum has been noted. This staining is due to an oxidation of the iron, ferric oxide, and is not in the least objectionable as it is non-irritating as proved by the fact that many thousands of patients operated upon in whom steel plates and screws have remained *in situ* from 5 to 28 years, are entirely unconscious of their presence, as there never have been any objective or subjective symptoms.

It is only reasonable to assume that at some time in the future an alloy may be produced which will have greater physical properties than vanadium steel, but it is doubtful if such an alloy will be of a non-ferrous nature.

CARREL TECHNIQUE

Carrel technique with sodium hypochlorite—0.5 per cent sodium hypochlorite and 0.9 and 0.10 per cent sodium chloride—is a prophylactic against infection as well as of great value in the treatment of suppuration.

The objection to Dakin's solution as made from bleaching lime is that it is unstable and caustic, necessitating the making and testing of a new supply every few days. For the past 18 years we have used to the exclusion of all other antiseptics and chlorines, a concentrated, electrolytically prepared sodium hypo-

chlorite of 4.05 per cent and sodium chloride 3.25 per cent, bearing the trade name "*Hypochlorite*," which has the approval of the Council of Pharmacy of the American Medical Association. Its great advantage is that it is stable and of low alkalinity and can readily be made available for use by the dilution of 1 part of the concentrate to $6\frac{1}{2}$ or 7 parts of water. It is an ideal physiological antiseptic as it destroys nitrogenous bacteria and necrotic tissue by the process of oxidation without inhibiting or in any way destroying viable cells or tissues, and I believe it would have met with the full approval of Lister.

Within a few years the antiseptics used today in the treatment of wounds—phenols, synthetic coal tar compounds, bichloride of mercury, potassium permanganate, peroxide of hydrogen, etc.—will be obsolete and many of the beautifully colored and attractively bottled proprietary antiseptics, whose chief value is confined to the test tube (not unlike iodoform gauze whose greatest virtue was its color and stench), will fall into disuse. It is interesting to note that of the hundreds of antiseptics which have been advocated during the past 50 years, very few have withstood the test of time—a rather sad, but true, commentary.

Those who decry the use of the Carrel technique, stating the same end-results can be secured with saline or other antiseptics, have little fundamental understanding or experience either with the method or of the chemical action of aqueous sodium hypochlorite. There is little or no opportunity for infection to take place in a compound fracture if an early débridement is done, and the Carrel technique is instituted at the time of operation.

The surgeon should be held responsible for postoperative infection if he fails to utilize the equivalent of a specific in the treatment of compound fractures—the Carrel technique—and he is open to fair and just criticism in view of the end-results which were secured by its use in the World War as well as in those clinics where it is used thoroughly and intelligently today.

The use of vaseline gauze packs or maggots has no place in the scientific treatment of compound fractures or their postoperative

complications, despite the enthusiastic advocacy of those measures. We are advised by the etymologists that the active principle of the maggot is an enzyme and to this property is ascribed the justification for the use of maggots in surgery.

We should not be hypersensitive to constructive criticism. There has been more or less hysteria associated with many of our very questionable practices. Criticism of other cults should be restrained until such time as we have "cleaned house."

COMPOUND FRACTURES

It has been the general opinion that steel plates and screws should never be used in the treatment of compound fractures. This opinion is based entirely upon theory and not on actual experience.

In 1933, George V. Foster, the author's associate, reported 304 consecutive compound fractures of the long bones treated by débridement, Carrel technique, open reduction, and plating when indicated. In this series over a 15 year period (1917 to 1932) 129 compound fractures were plated, there were no frank infections, and 1 amputation at the end of 3 weeks was necessary on account of the great loss of substance, bone and soft parts. There were 2 fatalities—one 4 weeks and the other 6 months after secondary operation. In the plated series the incidence of non union was 1.5 per cent while in the unplated cases, it was 40 per cent. The difference in the percentage ratio was most likely due to the extensive comminution found in the unplated series.

In our clinic we employ the following principles in all compound fractures regardless of their severity and have had but one frank infection since 1917.

1. A thorough cleansing of the wound and surrounding skin.
2. A conservative but thorough, debridement.
3. Reduction of the fracture—manipulation with or without internal fixation or skeletal traction.
4. The Carrel technique instituted immediately following operation as a prophylactic measure.

5. Immobilization of fracture, preferably with molded plaster of Paris, involving the proximal and distal joints.

6. Unsupported weight bearing not permitted until a strong bony union has taken place.

7. Plastic reconstruction if indicated, after cicatrization has been completed.

8. Physiotherapy—Morton Smart method of electrically graduated muscle contraction to restore muscle tone, active exercises.

INDIRECT OPERATIVE TECHNIQUE (Skeletal Traction)

Skeletal traction with ice tongs, Steinmann pin, Kirschner wire, etc., has been used in many clinics to the exclusion of other procedures. This is due either to the lack of knowledge of the non-operative technique and timidity or to the lack of confidence and inexperience in the direct operative attack. There is no question but that skeletal traction has an important place in the treatment of fractures, especially in extensive comminuted fractures. The percentage of infection (7 to 10 per cent) in 2 of the leading hospitals in the same city in this country is sufficient evidence that it is not without its dangers and complications. At best, skeletal traction is a 'bastard' form of the operative treatment. It must be used with discretion and only in those cases in which it is indicated. The 'robots' which have recently made their appearance, are of value in selected cases. It is an error of judgment however to expect to correct all displacements with this one procedure. A simple fracture is always more desirable than an incomplete compound fracture such as is produced in skeletal traction.

The literature abounds in reports of small groups of cases in which patients were treated by skeletal traction but contains very few reports of unsuccessful cases in which the complications, dangers, failures, etc., have been evaluated. In one case of skeletal traction of the femur in which ice tongs were employed we encountered a serious secondary hemorrhage. Like the operative attack, skeletal traction is not without its dangers and it will eventually find its proper place in the treatment of fractures but not to the

extent that it is being used today in many clinics to the exclusion of every other method

DIRECT OPERATIVE TECHNIQUE

The time-consuming, elaborate pre-operative preparation of the operative field, is unnecessary. Thorough cleansing of the skin with soap, water, and alcohol the evening of the day preceding operation, is sufficient. The operative field is prepared with either a 5 per cent picric acid or a 3 per cent tincture of iodine solution, is carefully draped, and the towels affixed. *At no time* are the fingers, instruments, gauze, catgut, etc., permitted to contact the skin. In other words, the non-contact technique of Lane is scrupulously carried out

TECHNIQUE OF OPERATION

Simple fracture of the femur. An external incision is made with a sharp scalpel through the skin and fat, after which this instrument is discarded. A tissue forcep and clean scalpel are used to undermine the skin and fat to permit of an ample exposure. Turkish towels are then carefully affixed to the cut skin edges with either Michel clips, Lane or Moynihan towel clamps, and the ends of the towels are fastened with Backhaus towel clips. The skin should not be exposed to the slightest degree as it is considered a source of contamination. The fascia lata is then incised and reflected. The vastus externus is incised and the cruræus muscle reflected and the fractured ends exposed. The proximal and distal fragments are not eviscerated into the wound or stripped free of their periosteal and muscular attachment any more than is absolutely necessary. A Lane or Lambotte clamp grasps the proximal or distal fragment and any intervening periosteum, muscle, or fascia is removed by curettage. The fracture is then reduced within the wound by traction and manipulation.

Immediately following the reduction, which is usually of a hair-line nature, a Lambotte or Lowman clamp is affixed to the site of fracture and a 6-screw plate is clamped to the external surface of the femur. The overall measurement, including the plate, is taken by a caliper in order to determine the exact

length of the screw necessary to engage the proximal and distal cortex and, at the same time, not to extend beyond the distal cortex. The bone is drilled through the proximal and distal cortex and a transfixion screw inserted. After a transfixion screw has been applied to both fragments, screws involving only the proximal cortex can be inserted. The drill can be either a hand or a motor-driven one, preferably of the twist type.

Great care should be taken to remove any periosteum at the site of the drill hole. Failure to do so causes the screw to twist about the periosteum and interfere with the proper cutting or tapping of the bone. After all screws have been inserted, the bone clamps are removed and all bleeding points carefully ligated as an absolutely dry wound is desired. The cruræus and vastus externus muscles are sutured with a figure-of-eight double No. 1 catgut, the fascia lata is closed with a double continuous chromic No. 00 catgut. Wherever possible, such as in the tibia, the periosteum should be gently reflected and sutured over the bone plate and screws with figure-of-eight catgut sutures. The skin is closed with Michel clips or with a vertical mattress silk suture and the fracture is splinted in a Thomas splint with Pierson flexion attachment; in fractures of the lower leg and forearm, molded plaster splints are used and are worn until firm bony union has occurred. Drainage is never used.

Recently we have had 2 non-unions due to too early weight-bearing after the patient's discharge from the hospital at which time bony union had been present.

If the technique, as described, is carefully followed, wound infection is no greater than in any other elective type of operation such as goiter, hernia, or chronic appendicitis. Bone plates and screws are not the source of infection as has been so frequently stated. Should infection occur, it is usually due to faulty technique or lack of operative skill on the part of the surgeon. If positive evidence of infection arises, with elevation of temperature, redness, swelling, or other symptoms, the wound should be thoroughly opened at once, all sutures removed, the bone plate exposed but allowed to remain *in situ*, and the Carrel technique instituted.

Those who have decried the use of steel bone plates have had little or no experience in their use. It is rather unfortunate that this criticism of those who have successfully used steel plates in the operative treatment of fractures, has retarded, at least 25 years the general scientific acceptance of the direct operative treatment here indicated.

BONE GRAFTING—PSEUDARTHROSIS

In a small percentage of cases non union will result whether steel plates and screws are used, or whether no operation has been done. Sufficient time should elapse before grafting is considered. This operation is not indicated in the treatment of acute fractures or for delayed union but for pseudarthrosis. Absolute fixation of the bone graft to the host, with 2 or more vanadium tap screws has greatly improved the immobilization of the bone graft and this is a very important and desirable factor. Fixation of fractures without motion is imperative until such time as bony union has occurred. There is little or no divergence of opinion as to the indications or technique where bone-grafting is indicated. Massive grafts are preferable. The step cut procedure is usually practiced with transfixion screws in the arm and forearm. The inlay in the tibia is the operation of choice and either an inlay or an onlay in fractures of the humerus and femur. In several cases, 2 grafting operations were necessary and in one case, 3 operations were done. In all cases bony union was eventually secured.

FACTORS CAUSING INFECTION

1 Too early operation. Simple fractures should not be operated upon until the swelling and blebs have subsided and the temperature becomes normal, which is usually, 10 to 14 days. The trauma caused by operation in addition to the already existing trauma, tends to produce necrosis of the tissues with resultant sloughing and infection. If operation is deferred 10 to 12 days it is usually bloodless and the postoperative reaction nil. We feel that this delay is of great importance and a large factor in combating infection and necrosis of tissue, obviously, compound fractures should be operated upon immediately.

2 Failure to carry out the non touch aseptic technique.

3 Excessive trauma caused by the rough handling of tissues and failure to carry out sharp dissection.

4 Lack of proper surgical armamentarium to facilitate operation. Most operations of this character should be completed in 35 to 45 minutes. The surgeon who procrastinates or prolongs the operation to 2 or 3 hours should either improve his technique or not attempt the operation.

5 Lack of an organized surgical team—that is, assistants and nurses. Failure to plan in advance and practice the meticulous technique, thereby causing many errors in the procedure and subsequent wound contamination. This failure of organization and team work is frequently the alibi of those who find it difficult to adjust themselves to such an exacting technique. With practice, the non touch technique soon becomes "almost automatic."

SUMMARY AND CONCLUSIONS

Frequently we have been accused of being guilty of operating on all fractures regardless of their nature. Nothing could be further from the truth. Those who have taken the time to inspect our records and x-ray films and note the end functional results in the patients operated upon, have been convinced not only of the necessity for the operation but are cognizant of the excellent end functional results secured. There is no legitimate excuse for neglect in the reduction of fractures any more than there is a legitimate excuse for anyone starving to death in a time of plenty. The vast majority of fractures can be satisfactorily reduced.

1 By the closed method, that is, by manipulation, traction and similar procedures.

2 By direct or indirect operative treatment, when indicated, and in clinics where conditions make such practice a safe procedure.

One of the large bone and joint clinics reports 33 per cent of the patients admitted have malunion or other complications following fractures. The same ratio exists in many

other clinics This is certainly not very complimentary to the initial treatment rendered and is evidence of the fact that much remains to be done to improve the methods of treatment and end-results.

The government of Australia and The Seamen's Hospital Society of Greenwich, England, have organized and instituted a study of this subject and are making constructive suggestions to correct conditions as they now exist If the medical profession fails to meet its responsibilities, the public undoubtedly will take the matter into its own hands and attempt to improve conditions through governmental or other agencies Such a situation would be a deplorable one, indeed, and the general practitioner and surgeon cannot evade this challenge The co-operation of the Council of Industrial Health recently created by the American Medical Association, together with the American College of Surgeons, can do much to improve present unsatisfactory conditions.

During the past 28 years the author and his associates have carried out the practices and

principles as herein outlined in more than 8,000 compound fractures and in cases in which osteosynthesis has been done. At first thought this large series would give one the impression of unnecessary operations However, when it is taken into consideration that a great majority of those injuries originated in an industrial army employing some 150,000 men engaged in the manufacture and fabrication of iron and steel, and the transportation of 200,000,000 tons annually of raw and finished materials, it is evident that despite all safety precautions, the handling of such great tonnage is certain to cause serious trauma.

The principles and technique which we have routinely practiced over these many years with such satisfactory end functional results, both from a humane and economic standpoint to the employee, employer, and surgeons, will be continued until such time as better methods are evolved which will improve the end functional results over the shortest period of time and with the greatest safety and comfort to the patient.

SOME PHYSIOLOGICAL AND PATHOLOGICAL OBSERVATIONS ON THE URINARY TRACT DURING PREGNANCY

J. MASON HUNDLEY, Jr., M.D., F.A.C.S., ISADORE A. SIEGEL, M.D.,
FRANK W. HACHTEL, M.D., and JOHN C. DUMLER, M.D., Baltimore, Md., and

THIS article deals with our continued studies of the urinary tract during pregnancy, the first portion of the presentation consisting of a summarized review of the physiological changes which we have previously published. Their reconsideration now is of value as the interpretation of the pathological processes which we will here consider are largely dependent upon these changes. We shall also report our findings in regard to the frequency of organisms found in the urine of normal pregnant women, which obviously have a very direct relationship to the incidence of inflammatory lesions arising during gestation. These inflammatory lesions and their treatment will also be considered.

Due to the pioneer work of Pierre Rayer and Cruveilhier, in the middle of the 19th century, on the question of dilatation changes in the urinary tract during pregnancy, great interest was focused on this heretofore undescribed observation. In the early days these findings were made at the autopsy table, later at operation, and not until the development of the cystoscope by Nitze was it realized that these dilatation changes were not of infrequent occurrence. With the introduction of intravenous urography made possible by the original work of Rowntree and his co-workers in 1923 and further developed by Swick and Binz in 1929, an increasing amount of investigative work has been done. Among the many investigators working on the urinary tract changes Duncan and Seng Lee and Mengert, P. Schumacher, Hofbauer, Dugald Baird, Kretschmer, Heaney and Ockuly should be mentioned. In our paper on the "Physiological Changes Occurring in the Urinary Tract During Pregnancy," we dis-

cussed in some detail the anatomical and histological changes observed, and also considered the causes of dilatation of the upper urinary tract. A summary of the more important findings will be referred to here.

From the intravenous urographic study of 27 normal pregnant women throughout the succeeding months of gestation and the puerperium, certain outstanding facts were brought out. We found the most constant change in the urinary system was a dilatation of the pelvis and calyces of one or both kidneys, a dilatation, tortuosity and kinking of one or both ureters, and a lateral displacement of these structures. Every patient showed some deviation from the normal, ranging from a slight dilatation to a marked degree of hydronephrosis and hydroureter. The right kidney and ureter were more affected than the left. The dilatation of the ureter always began at the pelvic brim, and in not one of the patients studied was there found a definite and significant dilatation of the pelvic portion of this structure. With the advance of pregnancy the dilatation of the upper urinary tract gradually increased, and we were unable to observe that it reached its maximum degree some weeks antepartum and then remained stationary until delivery. We feel that it is a gradual and progressive dilatation. Following delivery, there is a return of the urinary system to normal. We found that of 26 patients examined after delivery, 18 showed a return to normal in 28 days. However, 1 patient required 56 days. It is a well known fact that the presence of frank infection greatly retards the normal involution process. Figure 12 shows beginning dilatation of the ureters and pelvis of both kidneys at the fifteenth week of pregnancy. The 7 illustrations following are succeeding examinations of the same patient, beginning at the eighteenth week of pregnancy and continuing

From the departments of Gynecology, Obstetrics and Radiology of the University of Maryland.
Presented before the Clinical Congress of the American College of Surgeons, Chicago, October 25-29, 1937.

Fig 1. a, A P., 15 weeks Beginning dilatation of both pelves and lumbar ureters. Also slight dilatation of the right pelvic ureter. Fetus seen in the pelvis. b, M L., 18 weeks Dilated pelvis and calyces of right kidney. Dilated and kinked right ureter. Dilatation beginning at brim of pelvis. Slight dilatation of left lumbar ureter. c, M L., 22 weeks Increasing dilatation of right pelvis, calyces, and lumbar ureter. Very slight dilatation of left lumbar ureter with beginning outward displacement. Fetus well visualized in pelvis. d, M. L., 26 weeks No increase of dilatation of right pelvis, calyces and ureter since last examination. Fetus visualized, breech presentation, spine to the left. e, M L., 34 weeks. Increasing dilatation of right

pelvis, calyces and ureter. Left kidney and ureter appear normal. Fetus is visualized, breech presentation, spine to the right. f, M. L., 39 weeks. No increase of dilatation of right pelvis, calyces or ureter since last examination. Left kidney and ureter appear normal. Position of fetus—vertex presentation, spine to the right. g, M L., 1 week after delivery. Pelvis and calyces of the right kidney have nearly returned to normal, but there is still a moderate dilatation of the right ureter. h, M L., 6 weeks after delivery. The right pelvis, calyces, and ureter are now normal. Urograms have been outlined for better reproduction. (Courtesy of Am. J Obst. & Gynec, 1935, 30:625)

until the sixth week postpartum (Fig 1b, c, d, e, f, g, h). It was observed that the dilatation of the urinary tract occurred later in the primiparae than in the multiparae, whereas the dilatations were more marked in the former than in the latter group. We do not feel that the position of the fetus has any bearing upon the dilatation changes observed, owing to its frequent change of position. At

one x-ray examination, the fetus changed from a vertex to a breech presentation during the 15-minute interval between exposures.

An anatomical and histological study was then conducted on the urinary tracts of 13 parturient women, all but 2 dying at term. In only 1 patient was there an infectious process found in the urinary tract, multiple punctate abscesses being found in the cortex of the

Fig 2 (Legend on opposite page)

kidney. However, the bladder and ureters showed no evidence of inflammation.

In every case but one, some dilatation of the ureter was found, the right side being constantly more dilated than the left. It is frequently stated that the dilated, tortuous, and kinked ureters occurring with pregnancy are longer than those not so associated. However, this has not been our observation. The longest ureter was found to measure 30 centimeters and the shortest measured 17 centimeters. The average length was from 24 to 28 centimeters. The sacculated dilatations of the upper ureter give one the impression that there is elongation of the tract, which is not borne out by actual measurement. However, it will be noted later that lengthening of the ureter may occur when there is a marked infection present.

The gross appearance of the ureters associated with pregnancy had many points in

common. They all showed some degree of dilatation, usually on the right side, which always began above the brim of the pelvis. The lower end of the pelvic ureter was quite firm and rigid, whereas the abdominal spindle was always flaccid and ribbon like, with definite loss of tone. No evidence of stricture formation was made out either grossly or microscopically.

The ureter was sectioned at different levels, and preparations of the bladder, trigone, and urethra were also made. Microscopical study of these tissues showed varying degrees of hypertrophy of the musculature, edema, and increased vascularity. These changes seemed to go hand in hand with similar physiological changes occurring in the generative tract during pregnancy.

The most striking change seen in the urinary tract is the marked hypertrophy of the external longitudinal sheath of muscle bun

dles found encasing the lower end of the ureters, the sheath of Waldeyer. The opinion has been advanced that this hypertrophied sheath is the important causative factor in dilatation of the ureter. If this is correct, the dilatations should be bilateral and should begin at the bladder. Our findings have not supported this view, for we have shown that the changes nearly always begin at the pelvic brim and that the right ureter is much more frequently involved than is the left. (Fig. 2a, b, c, d, e, f, g, h)

The abdominal spindle of the ureter undergoes constant dilatation changes during the

latter months of pregnancy. The wall of the organ is thinned out, the mucosa is normal but quite low, and there is some hypertrophy of the circular layer of musculature.

It was difficult to determine definitely if hypertrophic changes occur in the bladder, as the size of the muscle bundles varies greatly, depending on the bladder being contracted or distended. However, it is our opinion that hypertrophy of the musculature does take place.

The trigone revealed definite hypertrophy of the muscle layers associated with edema and increased vascularity.

DISCUSSION OF URETERAL DILATATION AND ATONY

In order to determine if pressure played a definite role in the production of dilatation of the upper urinary tract, we decided to repeat the experiments of Lee and Mengert, who had studied the effect of continuous catheter drainage during the last months of pregnancy. They logically deduced that if these dilatations were produced by pressure, the relief of this pressure should allow the urinary tract to return to normal. However none of their cases showed any decrease in dilatation by the use of the indwelling catheter over a period of 74 hours. From their observations they are "skeptical that ureteral obstruction from any cause whatever, is the reason for dilatation of the upper urinary tract in pregnancy."

In our study we allowed the catheter to remain in the ureter 48 and occasionally 72 hours, with a resulting decrease of the dilata-

tion. We found that drainage for 24 hours was not sufficient to produce an appreciable change (Fig 3a, b, c). We also made intravenous urographic studies in the presence of large pelvic tumors and found that if these tumors were large enough to rise out of the pelvis and were of such configuration as to fit the pelvic bowl snugly they would produce dilatation of the upper urinary tract and that after their removal the pelvis and ureter would return to normal (Fig 3d, e).

Many explanations have been presented to account for the greater frequency of right sided ureteral dilatation. This is accounted for, certainly in part, by the fact that the left ureter is protected and cushioned by the overlying sigmoid flexure which is also a causative factor in the production of dextro-rotation of the uterus. The right ureter is also more exposed than the left due to its anatomical course, and therefore is more

easily compressed. The right ureter crosses the iliac vessels at nearly a right angle, whereas the left ureter runs almost parallel to the vessels (Fig 4).

In the intravenous urographic study of the normal pregnant women, which we have just described, it was found that with advancing pregnancy and with progressive dilatation of the ureter, the excretion time of the kidney was markedly retarded, so that frequently a delay of 30 to 45 minutes was necessary before a satisfactory film could be obtained. With this delay of excretion time, there is an associated atony and loss of irritability of the musculature with a resulting urinary stasis. This fact has been well shown by the work of Traut and McLane. These workers have been able to show that there is an increasing atony of the ureter with advancing pregnancy and that, at the end of the second trimester, there is a complete loss of tone with absence of peristalsis. There is a return of irritability during the last month of pregnancy with a period of atony following delivery. However, usually within 6 weeks postpartum the muscular tone has returned to normal.

A SUMMARY OF PHYSIOLOGICAL CHANGES OCCURRING IN THE URINARY TRACT

We have seen that the urinary tract undergoes certain definite changes during pregnancy and with the use of intravenous urography have studied these changes occurring in normal women in the succeeding months of pregnancy and the puerperium. The constant finding has been dilatation of the upper urinary tract and pelvis, the dilatation being more frequent on the right side and nearly invariably beginning at the brim of the pelvis. Following delivery, the urinary tract returns to normal in 4 to 5 weeks. This regression is delayed or never occurs in the presence of marked infection.

Histological studies of normal ureters associated with pregnancy have shown hypertrophic changes of the musculature, most marked in the sheath of Waldeyer. A definite softening process takes place particularly in the wall of the abdominal ureter, with this structure becoming flaccid and easily compressible.

Fig 4. Autopsy drawing of urinary tract, patient dying at term. Note right ureter crossing iliac vessels at nearly a right angle, thus making it prominent and more susceptible to pressure than the left ureter, which runs nearly parallel to the iliac vessels. (Courtesy of Am J. Obst. & Gynec, —Hundley, loc cit.)

We have shown that the pressure of the growing uterus impinges against the ureter, especially the right, at the pelvic brim, and that the resulting ureteral dilatation rarely begins prior to the sixteenth week of pregnancy. To confirm our belief that pressure is a factor in the production of the dilatation, we have seen that continuous drainage of the kidney pelvis with an indwelling catheter permits regression of the dilatation; also that large pelvic tumors cause pressure changes and that after their removal the urinary tract returns to normal.

In addition to these observations, we have noticed that with the advance of pregnancy the excretion time of the kidney was markedly delayed, and it was also noted that the dilated, tortuous ureter showed a decrease in

Fig 5 a Chorionepithelioma in a man primary focus being a teratoma of the testicle (X115) b Section of juxtavesical portion of ureter from man with chorionepithelioma

oma showing hypertrophy of the sheath of Waldeyer even more marked than that seen in pregnancy (X12) (Courtesy of Am J Obst & Gynec —Hundley loc cit)

rhythmical expulsive force due to lack of tone. In our original paper we presented certain evidence to show that the hypertrophic changes in the ureteral musculature, along with the increased vascularity, softening and loss of tone, were due to hormonal activity. The most convincing data were obtained from the autopsy of a man dying from a teratoma of the testicle with generalized metastasis, which proved to be chorionepithelioma (Fig 5a). Prior to operation the

urine had been strongly positive for prolactin on two occasions. The examination of the ureter showed definite hypertrophic changes throughout the entire organ but was most marked in the juxtavesical portion. Here there was tremendous hypertrophy of the sheath of Waldeyer, the greatest external diameter measuring 8 millimeters (Fig 5b). There was no evidence of any dilatation of the urinary tract which should have been present if the hypertrophy of the sheath (Waldeyer) is the etiological factor in the production of the dilatation. It is thought that the luteinizing hormone, prolactin B, is devoid of a growth promoting factor. In order to account for the hypertrophy of the ureter, the action must have been indirect. The prolactin elaborated by the trophoblastic tissue of the chorionepithelioma stimulated the testicle, with subsequent outpouring of growth hormone producing the described changes. This growth change produced by indirect action of prolactin is analogous to that constantly seen occurring in the generative tract of the female infantile mouse following the injection of pregnancy urine. Additional data which would seem to add to the evidence of hormonal activity on the ureter was obtained from an autopsy of a woman dying after an operation for an ectopic pregnancy of 7 weeks' duration. The lower end of the ureter showed a definite hypertrophy of the sheath of Waldeyer and there was no dilatation of the organ observed.

When one considers that the generative and urinary systems arise embryologically from the same anlage, we believe that it is not too speculative to deduce that the same hormones incidental to pregnancy, which produce increased vascularity, softening of the tissues, and hypertrophic changes of the musculature, would produce similar changes in the urinary system. We know that with the advance of pregnancy large quantities of anterior pituitary sex hormone and estrin are found in the urine. The luteinizing substance, designated as prolan B by Aschheim and Zondek, reaches its maximum excretion of 5,000 to 6,000 mouse units per liter of urine during the fifth month of pregnancy, whereas the excretion of estrin in the urine during early pregnancy is comparatively low and ascends to its maximum of 10,000 to 40,000 mouse units per liter in the last month of gestation.

It would seem possible that the urinary tract changes described could be brought about by these 2 hormones, the muscular hypertrophy and vascular changes being dependent upon the growth principle estrin, and the increasing atony of the ureter due to the relaxing influence of prolan B. The hypertrophic changes occurring in the lower end of the ureter in the patient dying following the operation for ectopic pregnancy of 7 weeks duration, were admittedly marked for this early period of gestation when the output of estrin was low. However, this finding does not necessarily preclude the possibility of such an explanation when we know how variable and individualistic the tissue reactions are to hormonal stimulation. Another factor that seems to support the endocrine theory is that following delivery and with the rapid decrease of the hormonal content of the urine, there is a progressive and rather rapid regression of the urinary tract to its normal state. These regressive changes would appear to go hand in hand with similar ones occurring in the generative tract postpartum.

In order to ascertain what effect pregnancy had upon the urinary tract of common animals, Mengert studied the ureters of 42 mammals of 8 species, half of which were pregnant and the other half being used as controls. He concluded from his observations that preg-

nancy has no effect upon the ureters of the animals studied.

Wishing to see what effect prolonged injections of estrogenic substance would have upon the urinary tract of spayed dogs, the following investigation was undertaken. Six healthy, medium sized, female dogs were selected, 2 of which were castrated, and on 1 an exploratory laparotomy was done to rule out pregnancy definitely, the ovaries were not disturbed. These 3 animals received daily injections of ammotin in oil¹ until each had received a total of 5,250 rat units the daily dose being 100 units. For each of these injected animals there was a control, 2 being castrated and the 1 remaining was a normal control for the non castrated injected animal. The summarized results obtained from this short study are as follows:

1. There was no significant change observed in the ureters of the castrated injected animals as compared with the castrated controls.

2. A marked growth of the uterus and vagina was obtained with definite hyperplasia of the endometrium and cornification of the superficial vaginal epithelium. In the urethra of the stimulated animals, the transitional epithelium was changed to a definite stratified type with cornification of the surface epithelium.

These investigations are being continued, for it is impossible to draw any definite conclusions based on such a small series of observations.

From our accumulated data we believe that the explanation for these constant dilatation changes occurring in the ureter is twofold. First, there is a preliminary softening of the ureter brought about by the hormonal activity. Second, the semicystic pregnant uterus impinges upon the prepared ureter at the pelvic brim. When the occasional dilatation begins at the bladder and is bilateral, the hypertrophied sheath of Waldeyer may be the etiological factor. When one observes dilatation occurring with large pelvic tumors, it may be argued that pressure alone is sufficient to cause this change during pregnancy. We are not of this opinion, for it would be impossible for the soft, pregnant uterus to exert ade-

¹Supplied through the courtesy of E. R. Squibb and Sons.

quate pressure on the firm, unyielding and unchanged ureter to bring about dilatation.

BACTERIURIA

After observing that the upper urinary tract during pregnancy undergoes dilatation and atony, ideal etiologial factors in the production of infection, we then began a bacteriological study of the urine of normal pregnant women

It is a well known fact that the normal kidney can excrete organisms with no impairment to itself or the remainder of the urinary system. It has also been noted by many observers that there is a high incidence of organisms occurring in the urine of pregnant women

With the developing stasis in the urinary tract and a high incidence of organisms in the urine of normal pregnant women, there should be a marked frequency of pyelitis. However, we found this occurrence of pyelitis infrequent. We felt that this could be explained by the organisms being for the most part confined to the bladder urine, while the kidney urine remained practically sterile

One of the first thorough bacteriological studies done on the urine of pregnant women was by Victor Albeck, in 1907. He found a very high incidence of organisms in both bladder and kidney urines. Every one of the 30 patients studied showed organisms in the bladder urine, and 70 per cent of the kidney urines were positive, the predominating organism being the colon bacillus. Other workers in this field agree as to the presence of organisms in the urine but their findings differ widely in regard to the frequency of their occurrence. From our observations, some of the discrepancies are more apparent than real, due more to the various interpretations of the findings than actual differences.

The results of several of the investigators are here quoted. Harris and Herrmann report bacteriuria in 74 per cent of their antepartum and 94 per cent of their postpartum patients. Duncan and Seng also found a high percentage of infections, 42 per cent antepartum and 80 per cent postpartum. However, Kinkaid, Dodds, Crabtree, and Prather found the occurrence of infection as low as 3 4 per cent,

6 4 per cent, and 13 per cent, respectively. The lowest incidence of colibacilluria has been reported by McLane and Traut, namely, 6 08 per cent for the bladder and 0 86 per cent for the right ureter.

Several factors enter into the determination of the incidence of organisms in the urine, some of the most important being the volume of urine and the type of culture media used. In the study of apparently normal asymptomatic women, there would necessarily be a small number of organisms present and their recovery would naturally depend upon the volume of urine, whether or not it is centrifugated, and also upon the culture media and duration of incubation. Another factor that has great bearing on the bacterial findings is the technique used in catheterization. Comparative deductions from results of various investigators are also difficult to determine, due to the lack of similarity of methods employed. Even the interpretation of statistical studies may be made to vary considerably in the same group of patients studied, depending upon whether the results are based on the total number of positive cultures taken, often several having been obtained on the same individual, or on the number of patients showing positive cultures.

As the reported results are at such wide variance, and there is such a paucity of comparative investigations between the bladder and kidney urines, we felt that further study of this problem was indicated. The plan of bacteriological investigation was carried out as follows:

1. A study of the bladder urine of 50 normal pregnant women.
2. A control study of the bladder urine of 50 normal non-pregnant women.
3. A cystoscopic study of 50 normal pregnant women with comparison of kidney and bladder urines.

An additional group of 100 normal pregnant women was also studied. but these findings will not be here included, for the methods and technique used were not similar to those of the recorded study.

Only patients who were asymptomatic and gave no history of previous urinary tract infections were used. The specimens were

obtained in the outpatient department, the most careful asepsis being employed. The technique was as follows:

1 Vulva and perineum scrubbed with green soap, sterile water and flushed with bichloride of mercury solution.

2 Labia and vestibule painted with mercurochrome, 5 per cent, and a sterile glass catheter passed into the bladder.

3 The first specimen allowed to escape, tip of catheter flamed, and second specimen collected in sterile tube.

The tubes were centrifuged and all but 3 cubic centimeters of the specimen pipetted off. The specimen was then shaken and 0.1 cubic centimeters streaked on a blood agar plate. Two brain broth tubes were also inoculated, each with 1 cubic centimeter of the urine, one being incubated under anaerobic conditions.

Bladder urine cultures were obtained from 50 normal pregnant women, and the results of the study are given in Table I.

TABLE I—BLADDER URINE CULTURES IN 50 NORMAL PREGNANT WOMEN

Organism	Positive	Percentage
Bacillus coli	3	6
Staphylococcus albus	15	30
Staphylococcus albus and streptococcus viridans	1	2
Streptococcus viridans	7	14
Streptococcus viridans and Neisseria catarrhalis	1	2
Streptococcus viridans and yeast	2	4
Streptococcus anhaemolyticus	1	2
Diphtheroid	1	2
Yeast alone	1	2
Negative cultures	18	36

As will be observed, there were 18 negative cultures obtained. The most important organism as an etiological factor in the production of pyelitis, the colon bacillus, was found 3 times. The *Staphylococcus albus* was found to be the offending organism in 16 instances and the streptococcal group in 12. This entire group of organisms is of low pathogenicity and the organisms are normal inhabitants of the epidermis of the labia and the mucosa of the vestibule and vagina. When one remembers that the external urinary meatus is nearly constantly bathed with cervical and vaginal discharges, it is somewhat remarkable that negative bladder cultures are obtain-

able, for certainly the urethra must contain organisms which are pushed into the bladder by catheterization. The coliform and coccal forms may, of course, under other conditions and locations, be highly pathogenic.

The results will be further analyzed, especially in regard to the incidence of positive cultures on the two types of media used.

A Positive cultures of all organisms on brain broth 33 cultures 64%

B Positive cultures of all organisms on blood agar 18 cultures 36%

C Positive cultures of *Bacillus coli* on blood agar and brain broth 3 cultures 6%

The variation between A and B, namely 14 cultures, is probably due to the difference in volume of urine used, the blood agar plate being inoculated with 0.1 cubic centimeters and the brain broth medium with 1 cubic centimeter, the lesser amount containing fewer organisms. All cultures were negative for strictly anaerobic organisms.

In order to determine if the incidence of the organisms described was peculiar only to the pregnant state, we decided to study a group of normal non pregnant women. Fifty normal, asymptomatic women as controls were selected. It was surprising how many patients in the outpatient department had to be interrogated and examined before the necessary number could be obtained. The results of this study are recorded in Table II, exactly the same methods were used as in the pregnant group.

TABLE II—BLADDER URINE STUDIES IN 50 NORMAL NON PREGNANT WOMEN

Organism	Positive	Percentage
<i>Escherichia coli</i>	6	12
<i>Staphylococcus albus</i>	5	10
<i>Streptococcus viridans</i>	4	8
Anaerobic streptococcus	2	4
Diphtheroid	3	6
<i>Alcaligenes faecalis</i>	2	4
Negative cultures	28	56

As will be noted from Table II, there were 28 negative cultures. Of the positive ones, 6 were due to the colon bacillus, this being twice the number occurring in the pregnant group. The same types of organisms, with the addition of the *Alcaligenes faecalis*, were found, the incidence of the *Staphylococcus albus* being 5 and that of the streptococcus being 4.

Here, as in the first study, the results will be further analyzed in regard to the incidence of positive cultures occurring on the two types of media used.

A Positive cultures of all organisms on brain broth: 22 cultures, 44%

B Positive cultures of all organisms on blood agar: 9 cultures, 18%

C Positive cultures of *Bacillus coli* on blood agar and brain broth, 6 cultures, 12%

The variation between A and B, namely 19 cultures, is probably due to the volume of urine used. All cultures were negative for strictly anaerobic organisms with the exception of 2, these being streptococci.

Comparative observations between the pregnant and non-pregnant group will now follow

A. Positive cultures of all organisms on brain broth in pregnant group: 32 cultures, 64 per cent

B Positive cultures of all organisms on brain broth in control group: 22 cultures, 44 per cent

C Positive cultures of *Bacillus coli* on brain broth in pregnant group: 3 cultures, 6 per cent

D Positive cultures of *Bacillus coli* on brain broth in control group: 6 cultures, 12 per cent

Here it is seen that the incidence of positive cultures in the pregnant group A is 10 more than those occurring in the control group B, 32 positive cultures in the former and 22 in the latter.

The next table shows the difference between the number of positive cultures in both groups when the medium is blood agar and the volume of urine used is 0.1 cubic centimeter. Naturally, the number of positive cultures will be reduced, due to the smaller volume of urine containing fewer organisms

A Positive cultures of all organisms on blood agar in pregnant group: 18 cultures, 36 per cent.

B Positive cultures of all organisms on blood agar in control group: 9 cultures, 18 per cent

C Positive cultures of *Bacillus coli* on blood agar in pregnant group: 3 cultures, 6 per cent

D Positive cultures of *Bacillus coli* on blood agar in control group: 6 cultures, 12 per cent.

The variation between A and B, namely 9 cultures, would seem to indicate that the number of organisms in the bladder urine of the pregnant group is greater than in the control group. It is also noted that the incidence of positive cultures of *Bacillus coli* in the con-

trol group is twice the number occurring in the pregnant group. The observation is of interest, for as we know this organism is greatly responsible for the inflammatory processes occurring during pregnancy. Therefore, one might expect a higher incidence of coliform organisms in the urine of the normal pregnant woman; however, this seems not to be the case in our study of this limited number of urines.

The last procedure in this bacteriological investigation was the cystoscopic study of 50 normal pregnant women, with comparison of the kidney and bladder urines. Due to the fact that *Staphylococcus albus* was found in 20 per cent of the bladder urines examined, a slight change was made in the catheterization technique. Instead of the extensive perineal preparation already described, we now cleansed only the vestibule and inner surfaces of the labia minora, the same solutions as well as the mercurochrome being used. It was thought that in preparing such a large area as was previously done, an increasing number of skin organisms might be brought into the field. This change in technique was of undoubted value, for in this series there was only one culture of *Staphylococcus albus* obtained. Another change in the procedure was to allow the urine to run directly on the media instead of inoculating from the urine collected in a tube. By this procedure, a volume of urine greater than that used in the previous studies was unavoidably allowed to run on the agar slant; therefore, the number of positive cultures here obtained on the blood agar and the brain broth, as will be later noted, nearly equaled each other. In this series the urine was not centrifugalized. With these aforementioned exceptions, the method of obtaining the specimens was the same as used in the previous groups.

The bladder was catheterized to obtain a specimen for microscopic study. Approximately 5 drops of urine were then allowed to run on the blood agar slant and 15 drops into the brain broth medium. The patient was then cystoscoped by the water method. As the possibility of infection in the right kidney urine is greater than in the left, due to the more pronounced dilatation changes in the right tract,

and as we also wished to obviate any unnecessary bacteriological work, only the right ureter was catheterized. Cultures were obtained from this kidney in the same manner as were those from the bladder.

Of the 50 normal pregnant women cystoscoped, 15 were selected in the early period of gestation, up to and including the sixteenth week, whereas the pregnancies of the remaining 35 were more advanced. The reason for separating the group into these two divisions was to determine if the dilatation changes in the upper urinary tract, which become definite about the sixteenth week of pregnancy, would be a factor in producing a higher incidence of organisms in the later weeks of pregnancy.

The cystoscopic examinations showed the usual changes that are found during pregnancy. There was no evidence of cystitis, the ureteral orifices were found somewhat high up in the bladder, and the frequent saddle depression of the superior surface of the bladder, due to the pressure of the enlarging uterus, was observed. These findings in detail have already been described by us in a previous paper.

Tabulated results of the findings in Series A, pregnancies up to and including 16 weeks, will now be presented. Of the 15 patients in this group, there was only 1 who showed an occasional leucocyte on microscopic examination of the bladder urine (Table III).

There were found in this series 11 completely negative cultures which are indicated by the blank spaces. The kidney urines were negative with the exception of 1 positive culture due to the colon bacillus. This organism in this patient was found on all media in the bladder, as well as in the kidney urine. *Streptococcus viridans* and a colon bacillus were found on both culture media in the bladder urine, but the kidney cultures were negative. Also, a diphtheroid was found in the bladder on brain broth media.

Tabulated results of the findings in Series B, pregnancies after the sixteenth week, will now be considered. Of the 35 patients in this group, 6 showed an occasional white blood cell in the bladder urine (Table IV).

In this series 20 negative cultures were found, as shown by the blank spaces in Table IV. As will be noted, only 1 patient showed a colon infection in both the bladder and the kidney urine on all media. Another gave nearly similar findings with the exception that the right kidney culture was negative on blood agar. The only other positive kidney culture was due to the *Staphylococcus albus*, it being positive in the brain broth medium of both bladder and kidney urine. There were 15 positive bladder cultures obtained from 35 patients. Four of these were of the coliform group, while 8 showed gram positive coccoid forms. Of the 3 remaining 2 positive cultures were due to *Neisseria catarrhalis* and the other to a diphtheroid organism. The same types of organisms were found in this series as in the previous one.

The summarized results of the cystoscopic study on 50 normal pregnant women, with comparison of the bladder and kidney urines, are as follows:

The examination of the fifty bladder specimens showed 19 positive cultures for all organisms, namely, 38 per cent. Some investigators base the incidence of bacteriuria on the number of cultures of colon bacilli found

all other organisms being considered as contaminants. Our incidence of bladder colibacilluria is 12 per cent. In regard to the 50 kidney cultures obtained, 4 of them were found positive, thus making an incidence of 8 per cent. Of the 4 positive cultures, the infecting organism was the colon bacillus in 3 and the remaining was the *Staphylococcus albus*. The incidence of the kidney colibacilluria was 6 per cent. Comparative deductions between Series A and Series B cannot be made with accuracy, for the latter is over twice as great as the former. However, there was found no marked variation between the number of positive kidney cultures in each group, in spite of the numerical difference: positive kidney cultures, Series A, 1; positive kidney cultures, Series B, 3. This would seem to indicate that the increasing dilatation of the ureter with atony and stasis, as seen with advancing pregnancy, does not in itself increase the incidence of organisms in the kidney urine.

Final deductions based on this completed bacteriological study are:

A. The incidence of positive cultures for all organisms in the bladder urine of 50 normal pregnant women was 64 per cent on brain broth and 36 per cent on blood agar.

B. The incidence of positive cultures for all organisms in the bladder urine of 50 normal non-pregnant women was 44 per cent on brain broth and 18 per cent on blood agar.

C. The incidence of positive cultures for all organisms in the bladder urine of the 50 normal pregnant women cystoscoped was 36 per cent on brain broth and 32 per cent on blood agar.

The data obtained from these studies would indicate that the incidence of all organisms in the bladder urine of the normal pregnant woman is high, namely 50 per cent of the 100 cases studied. However, this finding loses much of its significance when we note that the urine of the control non-pregnant group also showed a marked frequency of positive cultures, namely, 44 per cent. It is possible that there is a greater frequency of organisms in the bladder urine during pregnancy than in the non-gravid state. However, a far larger series of patients must be studied before this

and as we also wished to obviate any unnecessary bacteriological work, only the right ureter was catheterized. Cultures were obtained from this kidney in the same manner as were those from the bladder.

Of the 50 normal pregnant women cystoscoped, 15 were selected in the early period of gestation, up to and including the sixteenth week, whereas the pregnancies of the remaining 35 were more advanced. The reason for separating the group into these two divisions was to determine if the dilatation changes in the upper urinary tract, which become definite about the sixteenth week of pregnancy, would be a factor in producing a higher incidence of organisms in the later weeks of pregnancy.

The cystoscopic examinations showed the usual changes that are found during pregnancy. There was no evidence of cystitis, the ureteral orifices were found somewhat high up in the bladder and the frequent saddle depression of the superior surface of the bladder, due to the pressure of the enlarging uterus, was observed. These findings in detail have already been described by us in a previous paper.

Tabulated results of the findings in Series A, pregnancies up to and including 16 weeks will now be presented. Of the 15 patients in this group, there was only 1 who showed an occasional leucocyte on microscopic examination of the bladder urine (Table III).

There were found in this series 11 completely negative cultures which are indicated by the blank spaces. The kidney urines were negative with the exception of 1 positive culture due to the colon bacillus. This organism in this patient was found on all media in the bladder, as well as in the kidney urine. Streptococcus viridans and a colon bacillus were found on both culture media in the bladder urine, but the kidney cultures were negative. Also, a diphtheroid was found in the bladder on brain broth media.

Tabulated results of the findings in Series B, pregnancies after the sixteenth week, will now be considered. Of the 35 patients in this group, 6 showed an occasional white blood cell in the bladder urine (Table IV).

In this series 20 negative cultures were found, as shown by the blank spaces in Table IV. As will be noted, only 1 patient showed a colon infection in both the bladder and the kidney urine on all media. Another gave nearly similar findings with the exception that the right kidney culture was negative on blood agar. The only other positive kidney culture was due to the Staphylococcus albus, it being positive in the brain broth medium of both bladder and kidney urine. There were 15 positive bladder cultures obtained from 35 patients. Four of these were of the coliform group while 8 showed gram positive coccid forms. Of the 3 remaining, 2 positive cultures were due to Neisseria catarrhalis and the other to a diphtheroid organism. The same types of organisms were found in this series as in the previous one.

The summarized results of the cystoscopic study on 50 normal pregnant women, with comparison of the bladder and kidney urines, are as follows:

The examination of the fifty bladder specimens showed 19 positive cultures for all organisms, namely, 38 per cent. Some investigators base the incidence of bacteriuria on the number of cultures of colon bacilli found

catheter for continuous drainage. Despite these usually successful procedures, the patient became increasingly toxic, making it necessary to terminate the pregnancy at the thirty-second week. Unfortunately, the patient died, and the autopsy revealed a bilateral salpingitis, acute generalized peritonitis, bilateral pyelonephritis with marked hydronephrosis and hydro-ureter. There was found a left ureteral stricture, 6 centimeters below the ureteropelvic junction, and marked kinking of the upper third of both ureters.

The greatest degree of dilatation of the urinary tract that we have observed occurred in the presence of an inflammatory process. It is possible that the infection permits a greater degree of dilatation and atony as well as lengthening of the ureter to take place, for here the right ureter measured 34.6 centimeters in length and 21 millimeters in diameter at the pelvic brim, while the left ureter was 33 centimeters in length and 19 millimeters in diameter at the same level. Definite ureteritis was present and in the upper third of the left ureter a definite inflammatory stricture was found (Fig. 6; also Fig. 7a, b, c, d).

In the study of the normal urinary tract with pregnancy there was no instance of elongation or stricture of the ureter observed.

CLINICAL OBSERVATIONS

The symptoms of inflammatory disease associated with pregnancy are for the most part quite typical, and the diagnosis of the condition is usually readily made. The attack is often initiated with pain located in one or both kidney regions, the right being the most frequently involved. As is not infrequent, chills may usher in the seizure and continue throughout the period of intense infection. If one is to be successful in obtaining a positive blood culture, the specimen should be obtained just prior to, during, or just after, the rigor. Due to the associated ureteritis, pain at times is experienced extending down the course of the ureter, with its point of maximum intensity at the pelvic brim. When this occurs on the right side, the diagnosis of appendicitis may be made. At present, with our better understanding of

these urological problems during pregnancy, the unnecessary removal of the appendix is becoming less and less frequent. At times the pain may be intermittent, cramp-like in character, and located in the region of the pregnant uterus, not entirely dissimilar to early small labor pains.

The most frequent and constant symptom complained of is fever, its duration and elevation being dependent upon the severity of the infection. At the onset, the temperature is often quite high, 103 to 105 degrees, and is septic in type. There is also an associated increase in the pulse rate. With a mild infection, if there is no marked or extensive involvement of the kidney, the temperature will remain definitely elevated for only 3 to 4 days. However, its constant elevation without remission over a period of 6 to 8 days indicates extensive damage to the kidney, usually requiring the interruption of pregnancy.

Urinary symptoms are prominent features of this malady, for the most part consisting of frequency, dysuria, nocturia, and strangury. The urine is frequently of a turbid appearance due to the contained pus cells. Infrequently, hematuria may be present. With the intense infection at the onset, the output of urine is usually reduced in amount; this is due to the decreased activity of the swollen, infected kidney as well as to the partial trapping of the fluid by the very edematous ureteral mucosa. In this stage, the urine is concentrated and usually contains many clumped pus cells which are significant of an upper tract infection. However, at times these cells may be quite infrequent.

Gastro-intestinal symptoms of nausea and vomiting are of not infrequent occurrence, and usually abate quite promptly with the subsidence of the inflammatory process. An occasional observation of interest is that of jaundice, which is usually seen with the more toxic states. One patient was seen who was thought to have had acute yellow atrophy of the liver with intense jaundice; this cleared up promptly with appropriate urological treatment.

ANALYSIS OF CASES

This analytical survey is based on a study of 236 patients with inflammatory disease of

fact can be definitely stated. It would seem that the presence of these non pathogenic, or mildly pathogenic, organisms in the bladder urine of the normal pregnant woman is of little consequence and plays practically no role, *except under unusual conditions, in initiating the inflammatory processes in the urinary tract during pregnancy.*

From the cystoscopic study of the 50 normal pregnant women, only 4 of the kidney urines gave a positive culture, 3 of which were due to the colon bacillus. This finding shows that the kidney during pregnancy is for the most part sterile. The changed urinary tract, with its dilatation, atony, and stasis, is definitely more susceptible to the possibility of infection than is the unchanged tract of the non-pregnant woman. However, these changes alone are not sufficient to incite infection. Pyelitis develops only when there is an association of lowered resistance plus an influx of virulent organisms. The incidence of the organisms in the bladder and kidney urine is expressed by some on the basis of the number of cultures of colon bacilli present, on the assumption that the coliform group is the important factor in the production of pyelitis. If we follow this plan of considering all organisms other than the coliform group as contaminants and base our deductions only upon the frequency of this colon group we find that our incidence of colibacilluria of the bladder is 9 per cent and that of the kidney 6 per cent. The predominating organisms recovered belonged primarily to the coliform and gram positive coccal groups the latter predominating. Other occasional organisms found were *Neisseria catarrhalis*, *Alcaligenes faecalis*, and a diphtheroid. All of the organisms isolated from the bladder urine are normal inhabitants of the labial epidermis and mucosa of the vestibule and vagina. It would seem most likely that the vast majority of the organisms found in the bladder urine of the pregnant and non pregnant woman enter through the urethra. The comparative study between the bladder and kidney urines definitely supports this belief. Of the 50 patients cystoscoped, there were 4 positive kidney cultures and 19 positive cultures from the bladder. This would definitely rule out an

ascending infection and most likely a descending type as well.

PATHOLOGICAL OBSERVATIONS

We have shown that with the advance of pregnancy, changes take place in the urinary tract which are ideal for the development of infection. We have also shown that the incidence of organisms in the kidney of the normal pregnant woman is fortunately quite low, namely, 6 per cent. If the normal immunity of the patient is lowered and there is an increase of the invading organisms, an inflammatory process of the urinary tract may occur. This is particularly prone to happen if the patient acquired a pyelitis prior to pregnancy. The urinary tract may become involved by 3 routes of infection, the hematogenous, the lymphatic, and the ascending the first 2 being the most likely pathways. Each theory has its strong group of adherents, however I believe that the majority are of the opinion that the organisms are carried to the kidney by way of the blood stream. The evidence supporting these several theories will not be here considered.

Once the infection has become established in the "prepared soil" of the changed urinary tract, a definite train of symptoms develops, dependent upon the extent of the pathological process. In the presence of mild degrees of infection, pyelitis develops, the inflammatory process being confined to the mucous membrane of the pelvis and calyces. However, pyelitis as a distinct pathological entity is uncommon, for it is usually associated with varying stages of parenchymal involvement, punctate abscesses being frequently seen. This condition of pyelonephritis and also pyelitis is commonly associated with ureteritis the infection being for the most part confined to the mucosa. With an intense ureteritis localized fibrosis may occur, with resulting stricture formation. Carson, in his autopsy study of the urinary tract during pregnancy, found 3 patients who showed definite inflammatory strictures of the ureter. One of them, P. L. No. 1127, had been treated by one of us (J. M. H.) for a severe bilateral pyelonephritis by repeated ureteral dilatation, kidney lavage and the use of the indwelling

side, so that the gravid uterus can fall away from the compressed ureter and thus facilitate better drainage. The knee-chest position is more efficient but often impossible to maintain if the patient is toxic.

If the methods of therapy described prove of no avail, then cystoscopy with ureteral catheterization must be considered. At times, it is most difficult to decide when this method of treatment should be instituted. However, we feel that if after 6 or 7 days of medicinal treatment there is no alleviation of symptoms, ureteral catheterization is definitely indicated. This procedure was performed upon 25 of the 236 patients studied in this series, 10.6 per cent.

Stoeckel was one of the first to show that this method of treatment was of great value in the persistent and toxic type of pyelitis with pregnancy. Prior to this innovation, it was necessary to interrupt many of the pregnancies in order to save the patient's life. However, at present the termination of gestation is of infrequent occurrence. In this series of patients, 11 such interventions were necessary. It has also been observed that patients who show evidence of a rather intense infection may have a spontaneous premature delivery; this unfortunate outcome occurred in 20 patients.

In the severe type of urinary tract infection, ureteral catheterization with the establishment of better drainage frequently brings about most dramatic results. Even after one treatment, the symptoms may promptly subside and the temperature become normal. However, as a rule several catheterizations are necessary before such alleviation of symptoms takes place. If the response to these treatments is not satisfactory, the ureteral catheter may be allowed to remain in the ureter so that continuous drainage may be maintained, and frequent lavage of the pelvis, with dilute solutions of silver nitrate, may be carried out. It is not well to allow the catheter to remain *in situ* longer than 24 to 48 hours, for we find that its prolonged use in the last trimester of pregnancy is conducive to the early onset of labor. The explanation for this occurrence is probably due to the fact that the dilatation of the ureter by the

indwelling catheter causes afferent impulses, which, crossing the pathway of the sympathetic, readily produce a reflex contraction of the uterus, for, as we know, this organ becomes increasingly sensitive to stimuli during the last trimester of gestation, the most important causative factor probably being the cessation of progesterin activity.

Occasionally, in spite of the procedures mentioned, the patient remains severely ill, as shown by a gradual onset of lethargy associated with beginning urinary suppression, an increase of non-protein blood nitrogen, and continued elevation of temperature and pulse. When this situation arises, evacuation of the uterus is necessary. With this accomplished, ureteral compression is removed, good drainage is established and the urinary tract undergoes regression. This procedure was employed 11 times in this group studied and was successful in saving the life of every patient, with the exception of 1.

For the most part, we have always felt that the treatment of pyelitis during pregnancy was a palliative measure, mainly employed so that gestation might go on to term. We have also felt that we could not hope to cure the infection until after the termination of pregnancy, when the urinary tract has returned somewhat to normal and the provocative factors which tend to maintain the infection have disappeared. However, with the introduction of more modern chemotherapeutic agents, it would seem that the sterilization of the urine may be accomplished during the period of gestation. The present methods at our disposal for combating bacteriuria are the ketogenic diet, mandelic acid, and sulfanilamide.

During the past few years, renewed interest has arisen in the subject of urinary antiseptics, initiated in some measure by the work of Shohl and Janney, who showed that the growth of *Escherichia coli* was inhibited by changing the hydrogen-ion concentration of the urine. Some years later, Clark and Helmholtz introduced the ketogenic diet, its essential factor being the high fat content in relation to the carbohydrate component. Due to the incomplete metabolism of the fats, a condition of acidosis is produced with the out-

the urinary tract, admitted to the obstetrical wards of the Maryland University Hospital. With us, the incidence of pyelitis with pregnancy is 3.1 per cent, which corresponds fairly well with findings from other clinics. However, there is a widespread discrepancy observed between these various reports, the occurrence varying from 1 per cent to 14 per cent of normal pregnant women.

In the series of 236 patients reviewed, 136 were primiparae and 100 multiparae. We have noted that the degree of dilatation of the upper urinary tract is greater in the primipara than in the multipara. This may possibly be produced by the greater pressure on the ureter, which is caused by the uterus enlarging in an abdomen whose abdominal wall is less yielding to its growth. As a rule, pyelitis in the primipara is more severe than in the multipara; the temperature is higher, frequently 105 to 106 degrees, chills more frequent, and there is greater pain with more prostration and toxicity. Everyone agrees that stasis is one of the main factors in the production of urinary tract infection and this has a direct bearing on the time of occurrence of pyelitis. We found that pyelitis developed in only 11 patients during the first 16 weeks of pregnancy, for in this period the urinary tract is just beginning to show definite pressure effects and the incidence is naturally low. The frequency of pyelitis increases as pregnancy advances. In the middle trimester there were 32 such infections and in the last period 97, postpartum infections numbered 96.

It was noted that patients who had marked elevation of temperature and who were somewhat toxic were prone to deliver prematurely, in this series, 20 delivered spontaneously, while in 11 the pregnancy was interrupted artificially.

As we know, the colon bacillus is the most frequent offending organism, and so it proved to be in this series. The next most common type recovered was the coccal group.

Several of our patients gave histories of repeated attacks of pyelitis during succeeding pregnancies, however, others stated that they were free of infection during the pregnancies which immediately followed the one with the

initial attack of pyelitis, and that later the infection flared up in subsequent pregnancies. In others there was only one attack of pyelitis with the following pregnancies entirely normal.

TREATMENT

The treatment of the inflammatory lesions of the urinary tract during pregnancy falls into 2 main groups, namely, the medicinal or palliative and the operative or radical. Fortunately, the vast majority of these inflammatory processes respond to the medicinal form of therapy, as shown by this group of 236 patients, all of whom responded to these palliative measures, with the exception of 2, who required more radical procedures for their relief.

The type of therapy naturally depends on the condition of the patient, as evidenced by the extent and severity of the pathology. The great majority of these infections are confined primarily to the pelvic and ureteral mucosa and are frequently associated with varying degrees of pyelonephritis. The proof of the existence of mild degrees of kidney infection is difficult, for it is not until extensive parenchymal involvement has come about that significant changes in the phthalen and the non protein blood nitrogen are observed. For the most part the diagnosis of such a condition must be based upon the clinical findings.

During the acute stage of these infections, conservatism is the all important factor. The elimination of the kidney must be augmented either by the copious intake of fluids by mouth or if not well tolerated in this manner, subcutaneous or intravenous therapy must be instituted. If there is an elevation of the non protein blood nitrogen, as evidenced by nausea, vomiting, drowsiness and gradual urinary suppression the frequent administration of intravenous glucose is of the greatest value. The time honored practice of alkalization of the urine may be carried out although its efficacy is quite dubious as it has no specific action, for the colon bacillus will grow as luxuriantly on alkaline media as on acid media.

Another procedure that may be of value is changing the patient's posture from side to

pouring of ketone bodies in the urine, chiefly beta hydroxybutyric acid. It has been shown by Fuller that it is this ketone body in the presence of markedly acid urine that produces the desired bactericidal effect. The diet is difficult to carry out, as it frequently produces marked gastrointestinal disturbances which at times are distressing. We have discontinued the use of this diet in the treatment of urinary tract infections during pregnancy, particularly due to the fact that it produces a definite decrease in the carbon dioxide combining power of the blood, a condition not desirable at this time.

Our experience with the use of mandelic acid during pregnancy has been limited as well as not encouraging. This substance which is excreted unchanged is efficacious only in a markedly acid urine, the acidity being accomplished by the administration of ammonium chloride. This type of therapy necessitates the decrease of fluid intake, which would seem not desirable in the treatment of urinary tract infections at this time.

From the clinical and laboratory observations recently appearing from various clinics, it would seem that sulfanilamide is a valuable urinary antiseptic being bactericidal for the coliform and coccal groups, and is capable of rendering the urine sterile during gestation. Helmholtz and Osterberg state that sulfanilamide given by mouth produces a urine bactericidal for the organisms usually found in urinary infections, with the exception of the *Streptococcus fecalis*. Its ease of administration, its action in an alkaline urine, and its successful use in rapidly clearing up infections resistant to mandelic acid make sulfanilamide a urinary antiseptic of great value. Cook and Buchtel recommend the use of adequate doses of sulfanilamide if good results are to be obtained. They administer 30 grains (2 gm) the first day, 40 grains (2.65 gm) the second day, 60 grains (4 gm) the third day, and 40 grains (2.65 gm) each day thereafter.

Kenny and his associates have recently reported their results with sulfanilamide in the treatment of 16 patients suffering with pyelitis with pregnancy, due to the colon bacillus. In every patient treated, except one the drug appeared to bring about a rapid abate-

ment of symptoms and sterilization of the urine, the urine being free of pus and organisms in 2 to 5 days. They report one failure, a patient in her twentieth week of pregnancy, whose urine contained a heavy growth of an atypical coliform organism which proved to be resistant to sulfanilamide as well as to mandelic acid. In this group of patients treated, no other medication was used, neither was the diet nor the fluid intake restricted.

We have been somewhat hesitant in our use of sulfanilamide in the treatment of these urinary tract infections for it is still in the experimental stage and its mode of action is quite obscure. Probably we have been too conservative, but we have been loath to run the hazard of adding a possible toxic manifestation to an already ill patient. The recent literature is replete with accounts of these various manifestations which are at times quite alarming, but personally we do not know of a death that can be definitely attributed to the use of sulfanilamide. Long and Bliss give a note of warning as to the indiscriminate use of this substance, for it has certain serious toxic effects upon the hematopoietic system and they further state that its careless and reckless use is unwarranted and will undoubtedly result in fatalities. Here at the University Hospital Arnold, who has had considerable experience with this type of therapy in the treatment of streptococcal meningitis, believes that it can be used with safety provided the patient's progress can be carefully observed.

retina, choroid, and sclerotic with one strong scar. The actual area cauterized does not spread, and for this reason is definitely superior to the Guist and Lindner chemical cauterization method, or even the endothermy current used by Larsson, Weve, and Safar.

The operation The location of the retinal tear having been accurately ascertained by one of several methods, and sketches made of the fundus picture, the eye is irrigated with oxycyanide of mercury, 1:10,000 solution, and anesthetized by the instillation of cocaine hydrochloride, 4 per cent solution, or butyn 2 per cent solution, 1 minim, at 3 minute intervals for 4 instillations. A retrobulbar or subconjunctival injection of novocain solution, 2 per cent, 1 to 1.5 cubic centimeters is made, and 1 to 2 drops of adrenalin solution 1:1,000 is instilled to control bleeding. If butyn is used instead of cocaine, the cornea will remain clearer and ophthalmoscopic examination control becomes much easier. The conjunctiva over the area involved is incised parallel to and 10 to 12 millimeters distant from the limbus, and the conjunctival edges are retracted with silk traction sutures or suitable retractors. The exact area in the sclera overlying the tear is carefully ascertained, usually with the aid of an Amsler or Macky marker. The sclera is incised with a fine Graefe knife for a distance of 1 to 2 millimeters in length. If much fluid is present, the knife is rotated to allow escape of same, if little fluid is present, only a small incision is made and the knife is not rotated. The cautery, which has been previously heated to a white incandescence, is now plunged through the incision to the depth of 3 or 4 millimeters in such a way as to touch the retina. It is left in for only 1 or 2 seconds, never more. The conjunctiva is sutured with a single running loose suture, atropine sulphate unguentum, 1 per cent, is instilled, and both eyes are bandaged. The head of the patient is placed in such a position that the vitreous presses against the puncture hole.

The galvanocautery method This method has been extensively used in place of the thermocautery. Fine electrodes, slightly bent at the end, are used. Electrodes made with sharp points may be used to pierce the sclera more easily. Several punctures may be made

before the eyeball softens, the sclera being perforated to a depth of 2 to 3 millimeters, the cautery point being kept in about 3 to 4 seconds. One drawback is the important fact that the heat varies.

The Lindner-Guist chemical cauterization method. Both Lindner and Guist decided upon the use of potassium hydroxide after many poor results following the early successes with thermocautery and galvanocautery methods.

After subconjunctival or retrobulbar anesthesia injections, the site of the tear is marked on the bare sclera, the area is surrounded with a series of scleral trephinations, either a 1.5 or 1.75 millimeter trephine being used. The trephining is done very gradually in layers. Not every trephine opening is touched with the caustic. The caustic application is immediately neutralized with $\frac{1}{2}$ per cent acetic acid. Lastly, the choroid is perforated with a sharp canaliculus dilator.

The complications consist of piercing the choroid and allowing subretinal fluid to escape, and hemorrhage from an injured vortex vein or choroid.

However, large surfaces can be cauterized, especially necessary when large disinsertions are treated. The main disadvantages consist of the requirement of an exact technique of the trephining, the consumption of much time, and hemorrhage from the choroidal vessels.

Lindner used a so called undermining technique for holes in the macula. The idea is an excellent one, but the technique necessary is much involved.

Dialthermy or electrocoagulation This consists of two methods, viz: (1) surface coagulation with blunt electrodes; (2) electropunctures producing coagulation in the choroid.

Surface coagulation was given impetus by the reports from Larsson's clinic in Stockholm. He aimed at coagulating a large portion of the choroid, which produced an extensive retinochoroiditis with resultant closing of the tear. While an accurate localization of the tear is not so necessary with this method, Weve insisted that the electrocoagulations be placed directly over the region of the tear. A ball electrode 2 millimeters in diameter is held lightly against the sclera for 3 seconds, the

THE MODERN SURGERY OF RETINAL DETACHMENT

HARRY S. GRADLE, M.D., F.A.C.S. and SAMUEL J. MEYER, M.D., F.A.C.S. Chicago, Illinois

THE etiology of idiopathic detachment of the retina is in many cases confused, because the predisposing factors are combined. In the first place, there are two outstanding factors that favor the production of retinal detachment—myopia and trauma. Less marked predisposing factors are choroiditis of low degree, and senile degeneration of the retina. These four factors are the most important and either isolated or associated with each other, play a part in most cases of retinal detachment.

Slides of an eye recently examined histologically by Vogt, in which the retinal detachment was only several weeks old, reveal the fact that in fresh detachments there is no evidence of any inflammatory changes as postulated by Leber, Nordenson, Gonnin. There are no evidences of any inflammatory hemorrhages or bloodclots, nor of any scar formation, nor of any strand formation, nor of any inflammation whatever as a cause of spontaneous retinal detachment.

Finally, other predisposing conditions in this disease include hepatorenal insufficiency, dyscrasias, psychic disorders, and ocular fatigue. The causes which may produce symptomatic detachment are tumors, cysticercus, albuminuric retinitis, orbital cellulitis, scleritis, etc.

Recurrences after successful retinal detachment operations are very frequent. The correct percentage is not known at present. Kleiner, Larsson, Vogt, Weve, and others have written about this in the literature. Gonnin differentiates between recurrences which occur 2 to 3 weeks after surgical interference, and those which occur later. In the first cases, he believes that the original tear is not properly closed or sealed, or another tear has been missed or overlooked, or a tear may be present in an area which the ophthalmoscope cannot observe. In most of these recurrent cases, the cause probably lies in the great fragility of the

retina, which tears in a new place as soon as the original tear is sealed down. The fragility of the retina is a very important factor. The operation then becomes a symptomatic treatment. One must not overstep the limitations offered by each individual case, otherwise surgery will be discredited.

We close or seal through operations the end result of the causative factor or process of the retinal detachment, which rarefies or thins the retina and by this means can also lead to formation of tears, through which the vitreous enters behind the retina and results in detachment of the retina in a large proportion of the cases. There is, therefore, no reason why a case that has healed successfully after operation, should not develop a new hole or holes in the immediate vicinity of the healed area, where the retina has become pathologically thin or fragile, with a resultant recurrence of the retinal detachment. Following a recurrence, the surgeon should persuade the patient to have a second or third operation, as the rarefied or fragile area of the retina is usually limited in extent and may be successfully sealed or closed up. If the second eye is functioning properly, it may be more difficult to persuade the patient to have further work done. If the second operation is unsuccessful, or a recurrence develops, it becomes even more difficult to secure the patient's consent for a third or even fourth surgical procedure.

OPERATIVE METHODS FOR DETACHMENT OF THE RETINA

Gonnin thermopuncture method. One, of course, must begin with Gonnin's thermopuncture method which he so ably elaborated upon about 11 years ago. Gonnin chose this method because of the simplicity of instrumentation. This method has many advantages, especially when it is possible to reach the tears without much difficulty and when they are of such a nature that they can be sealed with thermopuncture. The scar, about 4 to 5 millimeters in width, is a firm scar which glues down the

retina, choroid, and sclerotic with one strong scar. The actual area cauterized does not spread, and for this reason is definitely superior to the Guist and Lindner chemical cauterization method, or even the endothermy current used by Larsson, Weve, and Safar.

The operation The location of the retinal tear having been accurately ascertained by one of several methods, and sketches made of the fundus picture, the eye is irrigated with oxycyanide of mercury, 1:10,000 solution, and anesthetized by the instillation of cocaine hydrochloride, 4 per cent solution, or butyn 2 per cent solution, 1 minim, at 3 minute intervals for 4 instillations. A retrobulbar or subconjunctival injection of novocain solution, 2 per cent, 1 to 1.5 cubic centimeters is made, and 1 to 2 drops of adrenalin solution 1:1,000 is instilled to control bleeding. If butyn is used instead of cocaine, the cornea will remain clearer and ophthalmoscopic examination control becomes much easier. The conjunctiva over the area involved is incised parallel to and 10 to 12 millimeters distant from the limbus, and the conjunctival edges are retracted with silk traction sutures or suitable retractors. The exact area in the sclera overlying the tear is carefully ascertained, usually with the aid of an Amsler or Macky marker. The sclera is incised with a fine Graefe knife for a distance of 1 to 2 millimeters in length. If much fluid is present, the knife is rotated to allow escape of same, if little fluid is present, only a small incision is made and the knife is not rotated. The cautery, which has been previously heated to a white incandescence, is now plunged through the incision to the depth of 3 or 4 millimeters in such a way as to touch the retina. It is left in for only 1 or 2 seconds, never more. The conjunctiva is sutured with a single running loose suture, atropine sulphate unguentum, 1 per cent, is instilled, and both eyes are bandaged. The head of the patient is placed in such a position that the vitreous presses against the puncture hole.

The galvanocautery method This method has been extensively used in place of the thermocautery. Fine electrodes, slightly bent at the end, are used. Electrodes made with sharp points may be used to pierce the sclera more easily. Several punctures may be made

before the eyeball softens, the sclera being perforated to a depth of 2 to 3 millimeters, the cautery point being kept in about 3 to 4 seconds. One drawback is the important fact that the heat varies.

The Lindner-Guist chemical cauterization method. Both Lindner and Guist decided upon the use of potassium hydroxide after many poor results following the early successes with thermocautery and galvanocautery methods.

After subconjunctival or retrobulbar anesthesia injections, the site of the tear is marked on the bare sclera, the area is surrounded with a series of scleral trephinings, either a 1.5 or 1.75 millimeter trephine being used. The trephining is done very gradually in layers. Not every trephine opening is touched with the caustic. The caustic application is immediately neutralized with $\frac{1}{2}$ per cent acetic acid. Lastly, the choroid is perforated with a sharp canaliculus dilator.

The complications consist of piercing the choroid and allowing subretinal fluid to escape, and hemorrhage from an injured vortex vein or choroid.

However, large surfaces can be cauterized, especially necessary when large disinsertions are treated. The main disadvantages consist of the requirement of an exact technique of the trephining, the consumption of much time, and hemorrhage from the choroidal vessels.

Lindner used a so called undermining technique for holes in the macula. The idea is an excellent one, but the technique necessary is much involved.

Diathermy or electrocoagulation. This consists of two methods, viz.: (1) surface coagulation with blunt electrodes; (2) electropunctures producing coagulation in the choroid.

Surface coagulation was given impetus by the reports from Larsson's clinic in Stockholm. He aimed at coagulating a large portion of the choroid, which produced an extensive retino-choroiditis with resultant closing of the tear. While an accurate localization of the tear is not so necessary with this method, Weve insisted that the electrocoagulations be placed directly over the region of the tear. A ball electrode 2 millimeters in diameter is held lightly against the sclera for 3 seconds the

applications being kept at a distance of 2 to 3 millimeters apart. A trephine opening or 2 is made in the coagulated area, the choroid perforated with a sharp scissors point, and the subretinal fluid is allowed to escape. The complications are few, except for a definite lowering of tension.

The strength of current used is 30 to 40 milliamperes. Weve used a 3 to 4 millimeter ball electrode with 100 to 150 milliamperes as a rule, the time being 2 to 3 seconds for each application.

Weve technique. Weve later changed from surface coagulation to the electropuncture method. Weve uses fine needles 0.2 millimeter thick and ranging from 0.75 to 1.5 millimeters in length. "Brushes" containing 4 to 5 such needles may also be used. The current used is 30 milliamperes. Longer needles 3 millimeters in length may first be used to assist in locating the tear. These punctures result in a white spot on the retina, about $\frac{1}{8}$ disc diameter in diameter, and are observed ophthalmoscopically. Then follows either the surface coagulation, the multiple puncture method, or a combination of both. A white flat scar results in the region of the tear. The scar is similar in appearance to the thermopuncture method of Gonin. It obliterates the tear and seals the retina down, and does not usually cause the formation of retinal folds and subsequently secondary tears.

The micropuncture method is now universally practiced throughout the world. The coagulation points have been varied by different operators such as the Salfar pins, Walker pins, Gradle electrode, etc. The essential end result is practically the same. The Walker pins require a moderately involved technique while the Gradle electrode is much simpler to use.

The electrolytic method of treatment of detachment of the retina. *katholysis.* Electrolysis was first attempted in the surgical treatment of retinal detachment toward the end of the 19th century. It has recently been revived by Vogt and Imre who have termed it *katholysis*. The main difference between this therapeutic procedure in those days and now is the importance of the accurate localization of retinal tears with the object of closing them through

a barrage of choroidoretinal lesions and sealed aseptically by chemical caustics or through the medium of such physical agents as heat and electricity.

The therapeutic principle of *katholysis* is to effect reaction through the liberation of sodium and hydroxyl ions at the point of the negative terminal which is inserted through the sclera into the choroid.

The technique is similar to that described for diathermy. The negative electrode consists of platinum-iridium needles 1, 1.5, or 2 millimeters in length, depending upon what part of the eyeball they are to be used. The positive electrode is attached either to an Arruga retractor or the patient's limb. Bubbles of hydrogen gas are liberated at the tip of the needle in the choroid. The current may vary from 1.75 to 3 milliamperes and is held in contact for 3 to 4 seconds.

The first puncture in the sclera is made as nearly as possible 2 millimeters behind the site where the retinal tear is judged to be, and the fundus is examined immediately after this. Bubbles of hydrogen gas are seen at the point of perforation of the electrode and these serve for intra ocular localization of the relation of the puncture to the retinal tear. The needles are inserted at intervals of 0.5 millimeters over this area as the scars produced by this method of treatment are small and do not appear to be more than 0.5 or 0.75 millimeter in diameter on ophthalmoscopic examination. The retina is shallow and at the macular and posterior pole of the eye a greyish white, fluffy edged cloud is readily seen at the point of the needle in addition to the bubbles. Surface coagulation with diathermy may be made to surround this area. The sclera is trephined as usual over this area or over the area where the fluid is most dependent. The choroid is punctured with a punctum dilator and the subretinal fluid is evacuated.

In favor of *katholysis* is the precision with which its effect on the ocular tissues is circumscribed. There is no extensive spread of the current and on this account no damage is inflicted on other intra-ocular structures remote from the area of operation. After *katholysis* there are usually not seen any complications such as cystitis,ritis, cataract, and

optic neuritis which follow in some cases in retinal detachment treated by any one of the surgical diathermy procedures.

Ophthalmoscopically the choroidoretinal scars appear to be 0.5 to 0.75 millimeters in diameter, are well localized, and do not appear to cause extensive fibrosis of the choroid and interfere with the absorption of the inter-retinal fluid. This is especially advantageous when operating in the region of the macula. In most cases of retinal detachment treated by katholysis, there are a few fine opacities in the vitreous over the site of the operated area for 3 or 4 weeks, but elsewhere this structure is very little disturbed.

The minute and well localized areas where the caustic effect of katholysis has operated are particularly advantageous in the treatment of a retinal tear at or near the macula where it is essential to avoid widespread damage to the adjacent retina and the optic nerve.

Another advantage of katholysis is its value in localizing the site of the retinal tear. At the point of insertion of the negative electrode through the sclera and choroid, a string of hydrogen bubbles about 2 to 3 millimeters long is to be seen, easily recognizable on ophthalmoscopic examination, these bubbles afford an important mark of the relationship of the puncture to the site of the retinal tear. In the katholysis operation when a retinal tear lies beneath the course of an extra-ocular muscle there is no need to divide it as a needle 4 millimeters long may be used to pierce the muscle fibers and then the sclera and choroid. Division of an extra-ocular muscle is, in some instances, necessary for the purpose of surgical access to post-equatorial parts of the sclera, but for the exposure of the sclera at, and in front of, the equator a muscle may be gently retracted by means of a double loop of No. 1 silk passed around its belly.

There are usually no intense reactions after katholysis with choroidal hyperemia and conjunctival chemosis as sometimes occur after diathermy and render the prognosis of some cases bad. Also there are no dense adhesions formed between the sclera and Tenon's capsule, a feature which makes exposure of the sclera a relatively easy matter if a second operation should prove to be necessary. After

surface diathermy the sclera and Tenon's capsule are so densely matted together that clear exposure and hemostasis are effected only after considerable trouble.

Some recent research work by Weekers on the surgical treatment of retinal detachment has shown the importance of the part played by plugs of organized granulation tissue which, passing through puncture wounds in the ocular tunics, adhere firmly to the episcleral tissues outside and to the vitreous within but not to the choroid and sclera on their way through these structures. The function of these granulation tissue plugs is to act as links between the outer surface of the vitreous and the episcleral tissues, in this manner holding the retina pinned back in juxtaposition with the choroid.

Up to date, insufficient histological examinations have been made after katholysis to ascertain whether this feature has any bearing on the success or failure of the katholysis operation when the negative needle has been deliberately passed into, or just through, the retina during the operation.

Other lesser advantages are concerned with the apparatus, which is simple in structure, reliable, sensitive, portable, and inexpensive. Among the disadvantages may be mentioned the lowered intra-ocular pressure after several punctures have been made with the kathode needle and some inter-retinal fluid has been lost. However, this does not make trephining at the end of operation insuperably difficult for with patience and care it may be effected without any untoward accident. We think that trephining is the most satisfactory method of draining the inter-retinal fluid. A trephine hole takes longer to close than the punctures with micro-pins and other such devices. Multiple fine punctures may all close simultaneously in a relatively short time whereas drainage from a trephine hole carefully placed and fashioned will be effective at least for several days after operation and in some cases for several weeks.

The tenacity of the choroidoretinal scar after katholysis is problematical. Up to date we have had the impression that the scars are too small and feeble to seal effectively a large retinal tear and some moderate sized holes in

the upper half of the retina in the majority of such cases

Katholysis with all its inherent advantages in the ease of operation, use of simple, inexpensive apparatus etc., has one definite disadvantage, and that is the fact that the resultant adhesive scar may not be of sufficient strength to keep the retina in place. We believe that if the area of katholysis is surrounded with a zone of Larsson's surface diathermy coagulation more fibrosis will be formed and a denser

adhesive process produced. Katholysis may also be combined with multiple diathermy micropunctures. The katholysis may be used to seal the tear proper, while the therapy in the surrounding area with either micropunctures or diathermy coagulation or surface diathermy coagulation, will tend to seal the surrounding retinal area more securely to the choroid. This latter method seems to be the best form of treatment offered with our present knowledge.

SOME PRINCIPLES INVOLVED IN SURGERY OF THE EXTRA-OCULAR MUSCLES

AVERY De H. PRANGEN, M.D., Rochester, Minnesota

IN general, the principles governing the surgical treatment of the extra-ocular muscles are identical with those governing surgery elsewhere in the body. Because of peculiar anatomical and physiological characteristics, however, there are certain aspects of these principles when applied to surgery of the muscles of the eye which may need reviewing. Surgery of the eye muscles is not a settled affair, and like all surgery it is in a constant state of controversy and change. It is well that this is so because such is the way of progress.

In discussing surgical treatment one cannot avoid stressing first the importance of diagnosis. A thorough and refined differential diagnosis tells us (1) what is wrong, (2) when to operate or when not to operate, and (3) indicates what should be done. It is my feeling that much of the confusion on these 3 points could be eliminated by more careful attention to the differential diagnosis. It is not enough that eyes deviate and have to be straightened. There are reasons why these deviations occur. A study of these reasons will usually determine that certain primary and secondary anatomical and innervational defects exist, and an attempt to evaluate the relative importance of these underlying defects greatly aids in understanding the type of muscular anomaly with which one is faced. By thus classifying cases according to disturbances of function, one should be in a better position to select the surgical procedure to correct them. Often several methods are available to straighten eyes, but one of these will be the best if it is possible to pick it. Differential diagnosis aids in such selection. The aim of modern surgical treatment of the eye muscles is restoration of function rather than mere cosmetic improvement. When function is restored, cosmetic results will be satis-

factory. In a previous paper¹ I discussed this relationship between surgical treatment and differential diagnosis more fully.

Several other factors must also be considered in deciding when to operate. These are the age of the patient, previous treatment, the present status of the condition as to whether it is improving or not, the accessibility of the patient for prolonged non-operative treatment, the type of patient (that is, his personality), and his social and economic status. The age of the patient is not as important as it was formerly supposed to be. Modern procedures, such as the recession operation and the use of catgut sutures, have made it possible to operate safely and accurately even at an early age. When proper non-operative management has been sufficiently tried and the defects are not improving or are becoming more marked, surgery is indicated at any age. Sufficient trial of non-operative measures should perhaps be from 6 months to 2 years, depending upon the individual case. In deciding to operate, one must consider the degree and nature of the strabismus, the condition of the visual apparatus, and the response or lack of response of the latter to treatment. It is granted that many patients can be cured by rather prolonged non-operative treatment, but the circumstances must be favorable. These circumstances are, as has been indicated, the accessibility of the patient for treatment, the type of patient, and the ability of the patient and his family to co-operate intelligently without economic distress. When these factors are unfavorable, it is perhaps better to operate than to permit these eyes to remain out of alinement. Spontaneous recovery of fusion and stereopsis are often noted after surgical correction when no other treatment has been given. I am heartily in favor of orthoptic training when surround-

the upper half of the retina in the majority of such cases

Katholysis with all its inherent advantages in the case of operation, use of simple, inexpensive apparatus, etc., has one definite disadvantage, and that is the fact that the resultant adhesive scar may not be of sufficient strength to keep the retina in place. We believe that if the area of katholysis is surrounded with a zone of Larsson's surface diathermy coagulation, more fibrosis will be formed and a denser

adhesive process produced. Katholysis may also be combined with multiple diathermy micropunctures. The katholysis may be used to seal the tear proper, while the therapy of the surrounding area with either micropin coagulation or diathermy coagulation, or surface diathermy coagulation, will tend to seal the surrounding retinal area more securely to the choroid. This latter method seems to be the best form of treatment offered with our present knowledge.

muscle pull by adding part of it to the reconstructed tendon. In preparing to alter the pull of a muscle, one must be sure to free it from all secondary attachments to the conjunctiva and the globe, particularly the latter. These secondary attachments, if unsevered, will prevent a muscle from being pulled forward or slipped backward, and may defeat either shortening or recession of a muscle. A tendon cannot be effectively shortened or recessed unless it is so freed. After completely isolating and freeing a tendon and muscle from all attachments, it is possible to resect about 15 millimeters of tissue, if so desired, as in the case of very paretic or paralyzed muscles. Tendon transplants from other muscles to assist in the restoration of action to paralyzed muscles are fairly satisfactory if one is radical enough in his dissection and preparation. In operating on these paralyzed muscles I prefer to shorten the muscle in addition to using the transplants.

In securing fixation or anchorage of the reconstructed tendon to the sclera, the aim is to secure firmness and permanency as well as correct anatomical alinement. Exact mathematical measurement should be employed in placing a new scleral insertion in either recession, resection, or advancement. The normal distances of the various insertions from the limbus of the cornea should be kept in mind and these should be altered exactly as required. Estimated changes are likely to be inaccurate. Various means have been adopted to secure firm anchorage to the sclera. Silk sutures have been used with different combinations and knots. When tension has been created, such as in resection and advancement, I object to multiple silk sutures tightly tied in the tissues because they produce strangulation and invite sloughing and necrosis. Also, silk, when used, has to be removed. This may necessitate further anesthesia, as in the case of children, and also invites the danger of pulling on or disturbing the newly united tissues. Splints, such as gold and steel plates, are used to hold the tendons which have been operated on in proper alinement, and we at the clinic have found the former satisfactory for tendons which have been subjected to extensive resection, thus creating much tension. We do not use gold plates routinely, however, but only in special

cases. At present we prefer catgut sutures for all operations on muscles of the eye, including conjunctival closure. We use plain, non-iodized, and non-chromic gut put up sterile in alcohol, the alcohol being easily rinsed off before the gut is used. We find No. 000 plain gut satisfactory for resections and tucks and we use No. 00000 plain gut for recession and for conjunctival closure. These sutures seem to hold sufficiently long for firm union to take place, and they produce a very minimum of reaction. In addition, they do not have to be removed. Except when buried in a tuck, all knots are tied outside the conjunctiva so that a minimal amount of gut is buried and has to be absorbed. The latter point is, I believe, important in producing less reaction; buried sutures no doubt cause more reaction.

Postoperative care is simple. The first principle of healing is quiet and rest. Both eyes are padded to keep them quiet. A firm, pressure roller bandage is used on the eye or eyes which have been operated on the first day. It is felt that moderate pressure controls the transudation of fluids and possible bleeding. The patient is kept in bed. Dressings are changed the following day and pressure is discontinued. Patients who have had recessions are allowed up and are dismissed from the hospital about the fourth or fifth day, the eye which has been operated on is uncovered the following day. Patients who have had resections and tucks are kept quiet in bed with both eyes covered for about 7 days; they are dismissed from the hospital on the eighth or ninth day with their eyes uncovered. When a muscle has been operated on a second time or when gold plates have been used because of the degree of shortening and the tension produced, the patient is kept quiet several days longer.

I am sure that rather marked and even severe reactions of the parts operated upon are quite often encountered. Such reaction consists of swelling of the upper lid and edema of the ocular conjunctiva. This appears about the third day; it is non-suppurative and reaches its height about the sixth day, when it gradually recedes. This reaction is probably a non-suppurative serous tenonitis of traumatic or chemical origin. While it is practically always harmless, it is nevertheless unpleasant and

ing circumstances are favorable. When orthoptic training is impossible or not feasible, I believe surgery should be resorted to more often. At least these eyes can be straightened and given a chance to overcome amblyopia and develop fusion by themselves when no other assistance is available.

One has a natural aversion to operating on both eyes at one sitting. When the patient is available, it is probably best to operate on one eye and then on the other at a later date. When patients come from a long distance and are unable to return for further treatment, however, it may be necessary to operate on both eyes at the same sitting. Whether to operate on both eyes or one is also determined, of course, by the severity of the defect and whether it is bilateral. When a bilateral defect exists, I think it is more proper to correct both eyes than to unbalance the eyes by trying to obtain correction by operating on one eye alone. In other words, one should attempt to restore normal function rather than to effect mere cosmetic straightening.

The type of anesthesia employed is important to both patient and surgeon, an efficient anesthetic greatly promoting the successful outcome of any operation. With an efficient anesthetic, much less trauma, physical and mental, is encountered and better work is carried out. The physical condition of the patient being satisfactory, I much prefer general anesthesia. It seems most difficult to obtain satisfactory local anesthesia. In the first place the patient is acutely conscious of the operator's every move and of the approach of instruments. Second, pain is caused by pulling on the long anterior ciliary nerves which run forward through the ocular muscles. Third, if the patient has been given sufficient opiates and barbiturates to be insensitive to pain, he might as well be asleep as far as our ability to inspect the eyes as we operate is concerned. At the clinic Dr. Lundy and his associates have developed intratracheal anesthesia to a point where it is eminently satisfactory. By this method the field is left entirely free. Pentobarbital sodium (nembutal) and when permissible morphine, are administered beforehand in adequate dosage to eliminate apprehension and to reduce greatly

the amount of anesthetic consumed. As a result of these procedures the patient comes out of anesthesia quietly and sleeps restfully for several hours. I am, of course, assuming that we have decided before the operating room is reached, by careful diagnosis, just what and how much is going to be done, and we seldom change our plan unless something of an unusual anatomical nature is encountered.

Regardless of the type of operation performed, there are certain fundamental procedures which are common to all extra-ocular muscle surgery. These are the incision, the isolation and reconstruction of tendons, the securing of anchorage or fixation to the sclera, and the use of various sutures and splints.

A properly placed incision giving adequate exposure of the field and room to work is most essential. I prefer a long incision through the conjunctiva, together with free and wide undermining of this tissue so that the important landmarks of the insertion, tendon, and capsule are freely visible. Too small an incision prevents the carrying out of such a procedure. As a corollary I also prefer a smooth and careful closure, using sutures enough to accomplish this. This gives smoother healing and less scarring and granulation. In incising, one should avoid injury to Tenon's capsule and the tendon itself, for all of these structures may be needed in the reconstruction. In incising and in isolating and reconstructing tendons one must have due regard for tissue welfare and aim at a minimum of trauma, which is a fundamental principle of all surgery. On the other hand one must be radical enough in these maneuvers to attain proper reconstruction. The best surgery at times may well be the most radical for one must not stop short of attaining the objective.

In reconstructing tendons one must consider whether he is faced with normal tendons, poorly developed or overly developed tendons, anomalous tendons or tendons that have previously been operated on. The type of tendon which is uncovered naturally determines in addition to the diagnosis just what type of reconstruction should be attempted. The nature and development of Tenon's capsule should also be noted, for it can often be altered to lessen muscle pull or can be used to reinforce

THE TRACHOMA SITUATION IN CHINA

PETER C. KRONFELD, M.D., Peiping, China

IT IS a great honor to be asked by your governing council to present a paper at your clinical congress. On receiving the invitation to speak on trachoma I found myself in the embarrassing situation of not being able to think of any new facts concerning this disease. Obviously, I am not expected to speak on the etiology of trachoma. Undoubtedly, you are well informed about the steady progress of the work of Thygeson, Julianelle, Harrison, and others, which has been done here in the United States, and which has carried the solution of the etiology of trachoma to a point where we hope it will soon cease to be a problem.

Obviously it would be like carrying coals to Newcastle if I spoke here on the modern methods of combating endemic and epidemic trachoma. You are all familiar with the methods and results of the campaign against trachoma which Gradle and his associates have been conducting in southern Illinois aided by the generosity and understanding of Governor Horner.

The most discouraging thought, however, for one who is asked to speak on trachoma at this time must be that only one year ago MacCallan, probably the most experienced clinical trachomatologist of this era, published a monograph which contains practically everything worth knowing about trachoma.

Through the repercussions in the newspapers of the Sino-Japanese conflict, I became aware of a growing interest of the world at large in the fate of the 470 million inhabitants of the Republic of China. The Chinese, who constitute the great majority of the population of the enormous country, have been described by one of their best connoisseurs, Dr. Hsien Wu, as "over-peaceful, non-persevering, non-progressive, non-enterprising, and easily contented with the environments in which they find themselves." It occurred to me that

you might be interested to hear how the Chinese have been defending themselves against one of their domestic enemies, namely, against trachoma.

There are only a few publications dealing with trachoma in China from the viewpoint of modern western medicine, and these publications are not easily accessible. I have had direct contact with Chinese affected with trachoma in the outpatient department and hospital of the Peiping Union Medical College, an institution with which I have been connected for the last 4 years. The patients seen there come chiefly from Peiping and its vicinity, that is, from the province of Hopei. In the Peiping Union Medical College, there is a special trachoma clinic for the employees of the institution. This clinic offers an excellent opportunity for continued study of trachoma cases, because attendance at this clinic is compulsory for trachomatous employees.

On various journeys through China, I have made observations with regard to the incidence and the general character of trachoma in rural districts of the provinces of Hopei, Chahar, and Shansi, and in the cities of Shanghai, Nanking, and Hankow. Before I shall try to tell you what my stay in North China has taught me with regard to trachoma, it might be well to investigate whether or not we agree in regard to the principal characteristics of trachoma.

Trachoma is a contagious chronic inflammatory disease of the human conjunctiva and cornea, in the course of which 4 typical stages can be distinguished. Severity and outcome of the disease vary greatly, due to differences in the virulence of the infectious agent and in the susceptibility of the individual. Pathologically, the disease constitutes an infiltrative, granulomatous form of inflammation which is followed by scar formation. The disease is self-limited. Partial removal or destruction of the conjunctival infiltration by surgical means, grattage and massage of the

makes one apprehensive lest increased tension from the edema may interfere with the stitches and healing. When this occurs, I have found intramuscular injection in the buttocks of boiled, whole, raw milk effective in hastening resolution of the edema, 5 to 10 cubic centimeters of such milk which has been boiled for 5 minutes, is used. On the second or third day after operation, when such a reaction is seen to be impending, an injection is given, and one injection is as a rule, sufficient. I believe such a procedure is more effective than iced or hot compresses which necessitate excessive manipulation of the eye which has been operated on. The less we manipulate and interfere with healing the better I believe will be the result.

Speaking in general of the after or end results of muscle surgery, I believe that I have seen far more under correction than over correction. If anything, one tends to do too little rather than too much. As I said earlier in this paper, I believe that we must be radical enough to attain our objectives. The immediate result is likely to be disappointing, as the muscles which have recently been operated on are sore and limp, and the final result may not be apparent for several weeks or even months, as

there is much readjustment which must take place in the complex muscle team of the two eyes after any muscle surgery has been performed.

SUMMARY AND CONCLUSIONS

A refined differential diagnosis is the first requisite of extra-ocular muscle surgery. In deciding to operate, one should be guided not so much by the age of the patient as by the degree and nature of the strabismus, the condition of the visual apparatus and the response or lack of response of the latter to non-operative treatment.

In reconstructing tendons, while due respect should be paid to tissue, one must nevertheless be radical enough to attain the desired objective.

Exact measurement should be used in altering tendon insertions on the sclera, plain gut sutures are preferable for securing scleral anchorage, and intramuscular injection of boiled, whole, raw milk has been found useful in controlling undue postoperative reaction.

It is felt that the surgeon is more likely to under correct than to over correct in operating for strabismus.

7.3 per cent were discovered to suffer from trachoma, whereas among the students over 10 years of age 28.9 per cent were affected with the disease. The incidence of trachoma increases considerably during the school age.

The incidence of trachoma in Peiping is not known, but such a figure would hardly be significant because of the large admixture of transient elements in the population of Peiping. More significant are the figures pertaining to rural districts with a stable population. Of such districts very few have been examined by competent ophthalmologists. Great variations as to the frequency of trachoma have been encountered. H. J. Howard has reported figures as high as 68 per cent (one village in the southern part of the province of Hopei). I have not found a village in the vicinity of Peiping in which the incidence of trachoma is higher than 45 per cent. The percentage of trachoma among the eye patients of the Peiping Union Medical College (2) is of some significance, because the majority of these patients come for the relief of diseases other than and apparently not related to trachoma. Between May 1, 1928, and April 30, 1929, 4,150 new eye patients were admitted to the eye out-patient department of the Peiping Union College; of these patients 33.6 per cent were found to have trachoma. According to H. T. Pi's estimate, at least one-third of the population of China suffer from trachoma.

With regard to the epidemiology of trachoma in China several factors are worth mentioning. Acute epidemics of ophthalmia, which are the principal propagators of trachoma in the Near East, are fortunately rare in North China. During my stay in China I did not witness a single epidemic of Koch-Weeks conjunctivitis. An epidemic of gonorrheal ophthalmia which broke out in one of Peiping's municipal institutions for the poor was described by my associate, Dr. T. H. Luo. There are, however, other factors which act as propagators of trachoma in North China. Water is very scarce and, therefore, expensive. For a family of 5 members the amount of water necessary for cooking and drinking may easily cost from 50 to 75 cents a month, an amount which, for the lowest classes, may represent one-fifth of the entire

income of the family. These classes must, therefore, be economical with the use of water. "The people not only wash their faces in the same basin and use not only the same towel, but also the same water" (H. T. Pi).

The dryness of North China accounts for its dustiness. The layer of loose sand which covers most of the land is stirred up by the slightest wind and carried into the conjunctival sac and into the respiratory tract of the inhabitants. Besides, North China is notorious for its dust storms which, as a rule, rage for 3 days and 3 nights and put the love of the foreigner for China to a test. This dustiness of the country accounts for the prevalence of mild degrees of chronic traumatic conjunctivitis which, in turn, causes a tendency to rub one's eyes frequently.

Another factor which propagates the spreading of trachoma in China is the so called "common-towel habit." The customers of restaurants, theaters and tea-houses are given towels soaked in hot water with which they wipe their faces, necks, and hands. If the towels were put in boiling water after each customer no objection could be raised to this habit. Actually, most of these towels go through the hands and over the faces of several customers before they are put into hot water again.

The mode of infection in North China must be that of direct transfer of virus from one eye to the other. The dryness of the climate and the absence of acute epidemics permit no other way of infection. The direct transfer is made possible through the intimate symbiosis between affected and unaffected people under conditions of great uncleanness. The uncleanness has its reasons in the dearth of water and in the poverty, ignorance, and carelessness of the population.

The result of all these and probably other factors is an incidence of trachoma of approximately 33 per cent. Commonly one finds that one or two members of a large family, despite intimate contact with the other members, have escaped the infection. Unilateral cases of trachoma are also not uncommon in North China. I feel that these observations alone warrant the presumption that the infectivity of trachoma in North China and the

hypertrophic conjunctival surface, and the application of various non specific drugs, namely mild corrosives, astringents, antiseptics, and tissue poisons, definitely hasten the course of the disease

Some parts of this definition may require modification or amplification. The involvement of the cornea in the trachomatous process has been included in the definition because Wilson, Thygeson, Busacca and others have shown that thorough examination with the slit lamp and the corneal microscope reveals evidence of pannus not only in every case, but also in very early stages of the disease. It is true that microscopic pannus is less common. The difference between microscopic and macroscopic pannus is hardly more than a quantitative one, expressing a difference in the severity of the disease. I, therefore, prefer to speak of pannus as a regular manifestation of the disease instead of calling it a complication. The exceptional cases in which the severity and extent of the pannus is out of proportion to the degree of conjunctival inflammation may deserve to be called complicated.

It might be argued that a definition of trachoma should include the statement that trachoma is a clinical and etiological entity. Such a statement will find general acceptance if one thinks of folliculosis and follicular conjunctivitis in this connection. These two diseases always prove distinguishable from trachoma if they can be observed for some time. Inclusion conjunctivitis of the newborn and of the adult, however, appears to be so closely related to trachoma that a non committal wording seems appropriate at this time, especially since Lindner suggests the name "paratrachoma" for that disease. Clinically, the difference between trachoma and inclusion conjunctivitis is marked. Corneal involvement and conjunctival scars are rare in inclusion conjunctivitis besides, the latter tends to be milder and shorter in course than trachoma. Etiologically, however, a close relationship between the two viruses must be admitted.

As another omission from the foregoing definition of trachoma, the fact might be considered that monkeys inoculated with material

obtained from human trachoma, regularly develop a disease which resembles follicular conjunctivitis in man. This is doubtless a significant fact because only the viruses of trachoma and of inclusion conjunctivitis and the diphtheria bacillus cause visible changes of the conjunctiva of the monkey. One must, however, be careful in naming this experimental disease of monkeys and in drawing analogies between it and human trachoma. Statements like "Trachoma has been produced in monkeys" or reference to the "trachoma of monkeys" meet with decided opposition on the part of important clinical trachomatologists.

The definition of trachoma as given at the beginning of this paper seems to comprise all the important features of trachoma on which we all agree and can, thus, serve as a basis for the discussion of problems pertaining to trachoma. The trachoma situation in China will be discussed under the following headings: (1) the incidence and epidemiology of trachoma, (2) the severity, course, and outcome of trachoma, (3) the treatment of trachoma.

INCIDENCE AND EPIDEMIOLOGY OF TRACHOMA IN CHINA

Following MacCallan, a rough idea of the incidence of the disease may be obtained by dividing the world into 4 categories according to the degree of trachomatous incidence: (1) practically universal, (2) very common, (3) occasional with heavy local infections, (4) rare. MacCallan puts China in group 1 where trachoma is practically universal. Also in group 1 are Palestine, Egypt, the Levant, Morocco, Algeria, Tunisia, Arabia, Persia, Iraq, Mongolia, Indochina, parts of Russia, Sardinia, Corsica, Cyprus, Malaya, and Polynesia. My feeling is that China should not be put in the same group with Egypt or Palestine.

The available data on the incidence of trachoma in China are incomplete and partly non representative. In the schools of Peiping one of my associates Dr S P Chang found, for children and youths between the ages of 5 and 15, an average incidence of 18 per cent. These students came socially from the middle classes. Of the children under 10 years of age

trachoma and militates against cure." I found it very difficult to assess the influence of such coexistent diseases upon the severity of trachoma. Only in the case of coexistence of trachoma and phlyctenular disease I became convinced that the two diseases were influencing each other unfavorably and that treatment of each disease was necessary to obtain noticeable improvement of trachoma or of the phlyctenular keratoconjunctivitis.

A sequela of trachoma which is characteristic for China is the plasmoma (10) of the conjunctiva, a well circumscribed nodular or sausage-shaped tumor which arises from the fornices or from the semilunar fold and consists of densely packed plasma cells. Although several types of such tumors are known to the pathologists, the plasmoma which is confined to the conjunctiva represents a definite clinical entity. Its relations to trachoma were established in countries where trachoma is less common than in China (Kreibig). In those countries, it seems, very few cases of plasmoma have been observed in which the presence of trachoma could be ruled out. Beyond this intimate relation to trachoma, nothing is known about the etiology of these plasmomas.

In our clinic, such plasmomas are very common, apparently more common than in any other trachoma country. All patients seen in one clinic exhibit signs of trachoma in its late stages, but there are, apparently, no relations between the severity of the trachoma and the occurrence of the plasmoma.

Thorough studies of our cases have revealed no systemic or local abnormal findings which could be correlated with the occurrence of the plasmoma. Pathologically, the plasma-cells which make up most of the tumor show moderate degenerative changes. A tendency toward hyalinization is fairly pronounced in the stroma and in the vessel walls of these tumors. The bulk of the tumor, however, even after duration of a year or longer, retains its typical plasmacellular structure.

These plasmomas respond little or not at all to contact radiation with radium. Our standard treatment is, therefore, surgical and consists of attempts at radical, but submucous, extirpation. Local recurrences are very rare.

TREATMENT OF TRACHOMA

Because of the small number of ophthalmologists who are practicing in China, mass treatment is the only form of treatment from which the country at large can benefit. While I have endeavored to do my share in the planning and working out of adequate measures of mass treatment for various localities in China, I have become more and more aware of the advantages which individual treatment possesses over mass treatment. I have become convinced of the immense value of daily clinical examinations of a small number of trachoma patients by the same ophthalmologist.

The benefit derived from such an individual scheme is mutual; as the clinical observations become more accurate, the doctor acquires a better understanding of the disease and, *pari passu*, the effectiveness of the treatment, based on such an understanding, increases.

Following the recommendation of Salinger (Chicago), local treatment of the trachomatous conjunctiva with quinine has been tried in my department and found to be very effective in the follicular forms. After the drug had been used for 2 to 3 months, the clinical picture became stationary and some of the patients developed a hypersensitivity to the drug.

Speaking in general, I have learned that the system (adopted by MacCallan and others), of alternation of treatment periods with copper sulphate, mercury bichloride, and chaulmoogra oil rubs, combined with surgical procedures of the order of grattage, is the most satisfactory one from the patient's as well as from the ophthalmologist's point of view.

In stubborn cases of stage III, I have also performed multiple microcoagulations (with the Weve needle) of the subepithelial island of infiltration. In almost every case this treatment resulted in a very noticeable improvement, that is, in a definite move toward stage IV.

In very severe cases of stage II or III, I have always kept the possibility of an extra-ocular systemic factor in mind and have carried out whatever measures were recommended

susceptibility of the Chinese are relatively low

During my stay in China I saw 4 cases of trachoma acquired by foreigners in China. In each of these 4 cases the infection could be traced back to a definite source, a case of active, amply secreting trachoma in a Chinese with whom the foreigner had had intimate contacts. The trachoma of the foreigner was in these 4 cases severe, in 2 of the cases it was confined to one eye.

SEVERITY, COURSE AND OUTCOME

My predecessors at the Peiping Union College, H. J. Howard and A. Pillat, the latter of whom now holds the chair of ophthalmology at the University of Graz, expressed the opinion that trachoma in China, as a whole, is of mild character and has a tendency to eliminate itself. This has, as far as I know, become the unanimous and fully warranted opinion of all ophthalmologists who have worked in China. The mildness of the disease is borne out by the fact that at least 25 per cent of the trachoma cases seen in a clinic or in a small population actually show a very mild form of trachoma and, as far as one is allowed to judge from the history of these patients, they never had a more severe degree of the disease. Students who come to us for the correction of refractive errors and give no history of even the slightest degree of conjunctivitis in the past and who have never received any conjunctival treatment, often show a mild stage (MacCallan, group 4) of trachoma. This finding is by some authors described as spontaneous cure. Spontaneous cure of mild or moderately severe trachoma is so common in China and other countries that I consider it as one of the characteristics of trachoma and have incorporated it in the definition given at the beginning of this paper. Trachoma is, in principle, a self-limited disease. The significant point in the aforementioned observation is that intelligent Chinese belonging to the middle classes often go through trachoma without noticing it. The commonness of this event in my opinion, again indicates that the disease tends to be mild in China.

The explanation that the Chinese does not become aware of his own trachoma because

he is less sensitive and has a lower degree of pain sense than other races is only partly pertinent. The pain sense of the Asiatic is, according to Jefferys and Maxwell and according to my own observations, just as acute and just as highly developed as that of any other race I know. It is only the lowest social class, the coolie class, which gives the opposite impression, but with them "it is not a question of suffering less pain, but of bearing it better. They are inured to lives of want, hard conditions, struggle and cheerful submission. They expect to suffer and expect little relief and care" (Jefferys and Maxwell).

In these lowest social classes it may very well happen that the subject's symptoms of mild or moderately severe trachoma are suppressed by the hardships which these people encounter in their struggle for a living.

Another observation which illustrates the mildness of trachoma in China is the great rarity of pronounced deformities of the tarsus. The milder degrees of entropion and trichiasis are, of course, common but a single Hotz operation, very often without removing slices of the thickened tarsus, is sufficient to restore normal position of the lid border permanently. Moderate degrees of posterior symblepharon are common and become noticeable and annoying when intra-ocular operations have to be performed. The shortening of the upper fornix is very often of such a degree that only a maximal muscular impulse will cause a sufficient degree of depression of the globe.

Xerophthalmus due to trachoma is very rare in North China.

The severe forms of trachoma in North China comprise about 25 per cent of the trachoma cases seen in a trachoma clinic. In a population their incidence is probably considerably lower. Just like the ophthalmologists in other countries, we have been interested to know whether it is the virulence of the infectious agent or the susceptibility of the patient which makes the trachoma in these cases take a severe course. According to MacCallan "some of the most severe cases of trachoma are seen in individuals, who are the subjects of ankylostomiasis, bilharziasis, malaria, or other debilitating diseases. Severe oral sepsis also contributes to the severity of

THE SURGICAL TREATMENT OF VARIOUS TYPES OF LESIONS IN THE PETROSAL PYRAMID

SAMUEL J. KOPETZKY, M.D., F.A.C.S., New York, New York

PATHOLOGICALLY it has become established that there are distinct variations in the location of the characteristic lesions comprising the infections of the petrosal pyramid. Therefore it seems fitting when determining the type of operation that shall be undertaken to meet the indications a given case presents, that the otological surgeon shall be able exactly to diagnose the location of the lesion which he is attempting to eradicate. Likewise it seems that there is small justification for allowing the surgical approaches toward eradication of purulent lesions in the petrosal pyramid to fall into the category of routine surgical procedures. Finally, so exact can the particularization in selecting the exact technique to meet a given situation be made, that the surgery employed should never be more extensive nor more radical than is absolutely necessary to accomplish the ends sought. Only in the rarest of instances is the clinical history so obscure, the laboratory data so insufficient, and the operating surgeon so at a loss as to the exact location of the lesion, that a general exploratory operation—that is, a surgical search of the interior of the petrosal pyramid for a lesion—is necessary.

Like infections of the appendix which should be adequately met by surgery before an intraperitoneal rupture takes place, or like a mastoidal infection which should be handled adequately by a surgical technique before rupture intracranially has taken place, so petrosal infections should be met with proper surgical intervention while the lesion is still intrapetrosally situated, and long before a rupture has taken place to add an extrapetrosal purulency to the gravity of the situation. That this can be done my personal experience

with 46 consecutive cases proves. It is both possible and feasible, and is the only rational method of meeting the surgical problem.

Petrosal infections, like any other infections in the body, have a tendency to heal spontaneously, and many petrous pyramid involvements do heal spontaneously. It is necessary that the surgeon confronted with a given case shall first determine whether his case is *progressing* or whether it is in *regression*, and in the process of healing. Space does not permit a detailed discussion of the details of diagnosis of petrosal lesions, or of the exact data on the differential diagnosis between petrosal lesions that are progressing and those which are in the process of spontaneous healing. Suffice here briefly to outline the important factors concerned in such a differentiation.

The clinical picture of a developing or advancing petrosal lesion may be summarized in the recognition of the significance of the reappearance of an aural discharge after a period of its cessation or its uninterrupted continuance after the performance of a complete simple mastoidectomy. Pain sensations appear periodically from branches of the first branch of the fifth cranial nerve with increasing severity and intensity, and with decreasing periods of intermission between them, until this pain is constant. There is present a low-grade temperature and an increasing general "malaise" and there is also present occasional transient inflammatory or irritative reactions from the living and functioning labyrinth. Concomitantly there may appear signs of involvement from other cranial nerves—from the sixth, the ninth, or the tenth—and occasionally also the facial nerve is involved. Added to these clinical findings is a roentgen film depicting varying degrees of halisteresis of the pars petrosa to complete obliteration of evidence of any bone structure. All these factors taken together form the

Presented before the Clinical Congress of the American College of Surgeons, Chicago, October 25-29, 1937.

by the internist syphilologist, otolaryngologist, or dentist whom I consulted. Occasionally I have noticed improvements of the trachoma following treatment of a general debilitating disease in the sense of MacCallan, or following the removal of definite foci of infection.

Thus, I have learned to consider such measures as a valuable adjunct in the treatment of severe cases of trachoma. The evaluation of these measures from the scientific point of view is still very difficult.

SUMMARY

The trachoma situation in China is, in several respects, a characteristic one. The outstanding fact is the mildness of trachoma in the Chinese. Compared with the other public health and economic problems which the Chinese government has to face, the author, although an ophthalmologist, is ready to ad-

mit that the trachoma problem is of minor importance.

the external auditory canal. Consequently, the differentiation between anteriorly and posteriorly located lesions becomes a rather simple matter. In a given case in which a simple complete mastoidectomy has been performed, a search of the postauricular wound will often reveal a purulent discharge in excess of what one would expect from a post-mastoidectomy healing wound, while the discharge from the middle ear is less intense and under less marked pressure. Therefore, when the pus seems to be coming from the mastoid wound, the first step in surgical therapy is to make a complete search of all the surfaces comprising the base of the petrosal pyramid—all of which can be done through inspection of the walls of the ordinary simple mastoid wound area. The skin may have to be re-opened, the granulation tissue which sprang up from the bone is removed, and the bone surfaces are carefully searched for fistulas. Generally one will be found either under the arch of the vertical semicircular canal or along the prefacial mastoid cell tracts leading toward the bulb. If fistulas in either of these areas or any other area emptying posteriorly through the base of the petrosal pyramid are located, the adequate surgery to handle this type of lesion is to be found in the enlargement of these fistulas, the curettement of their walls, and the drainage of the purulent accumulations from which they lead. No radical mastoidectomy is necessary to reach these lesions because they are accessible through the wound area left after the performance of the technique embraced in the simple mastoidectomy. Handled in this way I have had no cases in which a simple mastoidectomy was sufficient to locate and drain purulent fistulas, and recoveries ensued.

Failing to locate a fistula as described, radical mastoidectomy becomes the next necessary step; particularly so if, when inspecting the post-simple mastoidectomy wound area, no pus is found coming with more intensity than before from any particular wall area, or, on the other hand, there is now present a pulsating discharge from the middle ear spaces, pouring into the external auditory canal—evidence of pus under pressure which is apparently not coming from the

mastoid antrum or the epitympanic space, for then it would naturally drain into the open mastoid cavity. Here then there is presented an anteriorly lying lesion—one lying anterior to the cochlea. This cannot be reached with surgery limited to the technique comprised in the simple mastoid operation because the anterior cochlear area is not exposed by such a procedure. In my opinion, also, the dural approach should not be employed to reach it because then the dura is exposed to a trauma which increases the gravity of the prognosis. The most rational procedure is a complete tympanomastoidectomy to locate these lesions anterior to the labyrinth, and this naturally will include anterior supracochlear as well as subcochlear and precochlear situated lesions, and of course it will include enclosed empyemas of the so called pyramidal apex.

The performance of the radical tympanomastoidectomy will demonstrate the middle ear spaces full of detritus, pus, and granulations. Once these are cleared away, fistulas located in the tubotympanic orifice can be reached and drained successfully. My experience to date comprises 25 cases in which radical mastoidectomy was performed, fistulas found, enlarged, and their contents successfully drained.

Having performed a tympanomastoidectomy and finding no fistula, the symptoms meanwhile persisting—roentgen films continuing positive—the situation then presented logically leads to the deduction that the case presents the data upon which the diagnosis of an enclosed empyema of the so called pyramidal apex is present. Be certain that the case presented is one in which the lesion has become seated on a pneumatized temporal bone before making this diagnosis positively. Having made it, I believe that the operation of election to enter the petrosal pyramid and evacuate the enclosed empyema is that devised by Almour (1). This consists in removing the tensor tympani muscle from its bed and freeing the space between the Eustachian tube and the channel of the tensor tympani, and entering the petrosal pyramid at this point. There is pus under pressure from the inside, and a very slight opening into this tissue is soon rewarded by a gush of pus, and the

fundamental elements of a clinical picture which we recognize as indicating petrosal pyramid involvement

The paramount features differentiating a case in progression toward an intracranial involvement from one in regression or in the process of healing may be summarized as follows. A case is in progression when the symptoms of pain in and around the eyes change from a periodically present sign, and become persistent, eventually to cease suddenly altogether, likewise, the aural discharge which has been persistently present since the commencement of the symptoms from the petrosa, also quite suddenly stops or decidedly lessens in amount—the pus is finding egress elsewhere, when the transitory phenomena continue to present themselves with more frequent repetition, and when, in addition, a transient photophobia becomes evident, when a late appearance of a homolateral abducens palsy occurs or if such an abducens palsy were present earlier—present even before the simple mastoidectomy was undertaken—it does not show any immediate signs of improvement when in the face of a feeling of general well being, other and additional cranial nerves become involved, finally, when the usual signs of meningeal irritation appear there is slight pain in flexing the neck upon the chest, the patient becomes increasingly irritable, refuses personal “administration,” and “wants to be left alone,” indications of intensity of “malaise” and the whole appearance, attitude and behavior of the patient indicate to a competent clinician that the patient is sicker than before—this in the face of an afebrile condition, absence of eye pain, and a decrease of the aural discharge

On the other hand, a petrosal lesion is in recession when the pain in and about the eye, instead of suddenly ceasing gradually diminishes both in intensity and in duration of its periodic attacks, the intervals between its attacks are longer, likewise the aural discharge, instead of suddenly stopping, is gradually lessening in amount and there is less evidence of pulsation pressure noted otoscopically, when constant competent supervision and observation show that there are no transient phenomena presented due to irritative

reactions from vital structures located within the pars petrosa, when abducens palsy is present, it unquestionably shows itself as improving, lastly, when by attitude, behavior, and appearance, the clinician can be sure that the patient “begins to look better,” takes an increasing interest in his surroundings, and shows an improved morale. Under such circumstances the petrosal lesion is receding and spontaneous recovery is to be expected

Finally, when a petrosal lesion is recognized primarily every effort should be devoted to its exact localization, and a brief consideration of the factors entailed in making such a determination is in order

The surgeon, having diagnosed a case of petrosal lesion and then being confronted with the problem of its evident progression, must determine upon a procedure to stop further progress of the lesion. In the majority of cases, the surgeon is faced with a situation which develops after simple mastoidectomy. While it is true enough that petrosal infections are complications of tympanic involvements, the dramatic clinical picture of the mastoidal infection overshadows and beclouds the less intense petrosal tissue reactions, and these latter become significant only after the dramatic episode of the mastoid infection has been removed. Now, an attempt should be made to localize the petrosal lesion because upon the success of this localization will depend the selection of the type of surgical intervention logically to be undertaken to reach the purulent lesion in the petrosal pyramid. If one takes the bony labyrinth as a structure which is a fixed landmark, always constant in its position in the temporal bone, it is possible roughly to divide the lesions which occur posteriorly to the labyrinth and those that occur anteriorly to the labyrinth. Post labyrinthine lesions have a natural tendency to drain backward into the mastoid wound cavity. They do not seem so straggles to affect the middle ear structures and do not usually drain into the tympanic cavity. Anteriorly lying lesions—that is lesions lying anterior and internal to the cochlea—have a natural tendency, on the other hand, to drain into the tympanic cavity and the pus finds egress through the membrana tympani into

tions are all devised to keep the surgical field within the limits imposed by the boundaries of the temporal bone and no uninfected tissue need be touched, and no pus need be drained into sterile areas from the purulent contents of the petrosa. To do so adds extra hazards to a situation already grave enough.

Finally, every otological surgeon must be competent to perform all the recognized techniques upon the petrosal pyramid, so that he may select the one suitable for a given lesion, rather than be perfect in one procedure and habitually perform it, whether or not it meets the indications presented. Surgery, of course,

should be as conservative as adequacy will permit. True conservative surgery is ideal when it reaches its objective. Surgery which fails to accomplish this goal is neither conservative nor adequate. It is futile.

establishment of a surgical fistula which, subsequently enlarged, drains the contents of the empyema without bringing the purulency into contact with dura or other vital tissue structures

To date I have performed the Almour technique 8 times for an enclosed empyema of the petrosal apex. In all of these cases the integrity of the cranial cavity has been protected, and it is to this added factor that I attribute the excellent results that have followed.

There are cases which are seen too late, there are cases in which signs of meningeal invasion and infection are present, which are evidently progressing and which present intracranial symptoms in spite of drainage of fistulas. Furthermore, there are cases in which intracranial rupture occasionally has taken place prior to their reaching competent observation, or prior to clinical recognition of the petrosal lesions, finally there are cases in which a rupture takes place into the posterior cranial fossa area anterior to the cochlea, and as far as I know there is no surgical procedure which will permit both an inspection of the mesial walls of the petrosal pyramid and the location and adequate handling of a posterior fossa extradural lesion except the technique recently suggested by Lempert (2, 3). This technique is a modification and an improvement on that advocated by Ramadier. It consists in the removal of the tympanic plate which is the anterior bony wall of the external auditory canal below the petrosquamous suture. Bringing into view the carotid artery, working away from the artery the bone of the petrosal pyramid is removed piece by piece until its entire interior is under direct visual inspection. To make room, the tegmen tympani and the wall supporting the dura of the middle cranial fossa are removed. Perforations on the posterior fossa wall are disclosed if present, and may be handled just like perforations in the mesial wall of the mastoid process. To date I have performed this operation 3 times with no injury to the functioning of the mandible, and with complete recovery of the patients.

In the technique of managing petrosal infections it thus becomes evident that one meets

increasing severity of symptoms with a proportionately more extensive surgical attack, and only in the last instance is it necessary to invade the cranial cavity surgically.

Summarized, my cases to date consist of 46 cases of proved purulencies of the petrosal pyramid. Of these, 10 were cases in which the lesion was located posterior to the labyrinth. In 21 cases the lesion was located anterior to the labyrinth. In 4 cases there were combined anteriorly and posteriorly lying lesions. Seven times I found an enclosed empyema of the petrosal pyramid. Among these cases 11 times meningitis was present prior to my operative attempts and of these 11 cases of meningitis, 4 died. Among the other cases there were 4 additional deaths, in all there were 8 deaths, 37 cases were cured, and summarizing these cures—10 were cured through the performance of a simple mastoidectomy combined with the location and drainage of fistulas, 25 required radical mastoidectomies combined with the location and drainage of fistulas, 8 times I used the Almour technique and 3 times I used the Lempert technique, in both the Almour and the Lempert procedures, a radical mastoidectomy is a necessary step in the technique.

CONCLUSIONS

Petrosal lesions are vastly different from each other, and no routine procedure is commonly applicable to all of them. The integrity of the cranial cavity should be protected from all hazards—even those of a surgical nature—and no lightly conceived technique should be undertaken to reach intrapetrosal parts by violating the integrity of this cavity and endangering its contents. The application of elaborate techniques to reach the petrosal pyramid through the uninfected tissue of the neck or of the pharynx, is not based on much actual experience. They may be characterized as "cadaver operations" rather than practical surgical procedures, and should not be attempted to handle any of the lesions that petrosal pyramid infections present, because all lesions can now be reached by a proper selection of the type of operation to reach the locality where the lesion is located intrapetrosally. These opera-

able proof that the squamous cell carcinoma may arise from the epithelial lining of the Eustachian tube. In one of my patients, a male, aged 34, who complained of a feeling of fullness in one ear and demonstrated changes in the tympanic membrane, examination failed to disclose a lesion in the nasopharynx although the presence of one was perfectly obvious because of carcinomatous metastasis to the cervical nodes. Repeated biopsies from the nasopharynx in the region of the Eustachian tube failed to reveal the primary cancer. Postmortem examination, however, showed extensive destruction of the base of the skull and a carcinoma within the Eustachian tube, but no malignant invasion of the epithelial structures of the nasopharynx. I strongly suspect that a goodly number of such lesions, which encroach upon the cranial nerves and produce lymphatic metastasis to the cervical glands, arise from the epithelial lining of the Eustachian tubes but remain obscure for the duration of their life. Their clinical behavior points to the fact that they tend to migrate toward the jugular foramen with ravaging effects upon osseous tissue and profound disturbances of the cranial nerves which lie in their path. We cannot emphasize too strongly the fact that malignant lesions of the nasopharynx show a predilection for the lymphatics about the Eustachian tubes and find in this pathway an easy approach to the base of the skull. Of practical importance, therefore, is the observation that these new-growths often assume enormous proportions and consequent destructive behavior long before there is unmistakable evidence of their existence. It is this clinical characteristic that is frequently responsible for our failure to recognize the presence of these lesions until signs referable to one or more of the cranial nerves dominate the picture. Malignant disease of the nasopharynx presents a most provoking clinical problem and one with a prognosis as futile as that of cancer in any field within the domain of the otolaryngologist.

SYMPTOMATOLOGY

One of the earliest indications of a neoplasm in the nasopharynx is pain vaguely referred

to the posterior nares or more frequently reflected downward along the lateral wall of the pharynx or into the ear. This pain is usually sharp and lancinating in character, occurring in intermittent twinges as observed in the typical forms of neuralgia. Associated with this disturbance is a persistent vague sense of discomfort within the ear. The patient complains of an annoying feeling of fullness or a stuffy sensation in the ear, and inspection of the tympanic membrane frequently reveals those changes which point to a disturbance in the ventilation of the tympanum. The drum head is retracted, liver-colored, and occasionally casts a bluish tinge disclosing the effects of negative pressure in the tympanum with associated circulatory disturbances within the middle ear and Eustachian tube. When these signs and symptoms are the result of neoplastic invasion of the nasopharynx, the indications of metastasis to the posterior cervical lymph glands occur with amazing regularity.

In a series of 40 cases of malignancy of the nasopharynx, 11 patients, or 27.5 per cent, came to the clinic complaining of swollen glands in the neck. It was the first evidence of the disease in a large proportion of our cases and was present in 60 per cent of our group at the time the diagnosis of malignancy was definitely established.

It is to be noted that the following symptoms or clinical findings are usually the first indications of neoplastic invasion of the nasopharynx and the occurrence of any one or a combination of them should excite the suspicion of the presence of such a lesion: (1) glandular swellings in the posterior cervical chain; (2) pain referred to the ear or throat; (3) unilateral deafness or a stuffy, full sensation in the ear; (4) changes in the tympanic membrane.

We must not fail to emphasize the importance of these signs and symptoms. Too frequently, the otolaryngologist passes them by without recognition of their significance as early manifestations of malignant disease and without careful scrutiny of the nasopharynx. An appalling number of patients suffering from this affliction have failed to obtain a correct diagnosis, because the consultant did not

MALIGNANT NEOPLASMS OF THE NASOPHARYNX

A C FURSTENBERG, M D, Ann Arbor Michigan

ALTHOUGH much has been said concerning malignant disease of the nasopharynx, the subject is one which possesses innumerable opportunities for clinical and laboratory investigation. Controversial opinions concerning the pathological derivations of neoplasms of the nasopharynx, changing views referable to the spread of the disease, and diverse judgments in regard to therapeutic measures to be employed in the treatment of this malady, justify an evaluation of our present day knowledge and permit us to make another presentation of this subject. Perhaps I may prove this text worthy of reiteration by endeavoring to plow under superfluous and redundant postulations, and retain for correlation that knowledge and information which is of practical value in the recognition and treatment of this disease. To this end I shall bend my further efforts.

Malignant tumors of the nasopharynx may be classified into 4 groups, depending upon their tissue derivatives and mode of origin. The first is the carcinoma developing from the epithelial structures of the nasopharynx, second, the sarcoma, taking its origin from the connective tissue elements, third the lymphoblastoma, arising from lymphatic structures, and last, the tumor of teratological origin, representing misplaced or supernumerary cell collection which may proliferate and undergo malignant degeneration. The last type, namely the teratoma, should not be classified, perhaps, with the preceding neoplasms because they may take their origin from any or all of those elements which form the anlage of the first 3. Nevertheless, they are occasionally found in the nasopharynx undergoing malignant alteration and should be given recognition in a clinical study of this character.

The vast majority of malignant neoplasms encountered in the nasopharynx are epithelial

in origin and fall into the group of squamous cell carcinoma. We know little or nothing concerning the etiology of these lesions. Whereas we may theorize on the causes of carcinoma of the lip, the etiology of malignancy of the larynx, and the factors which influence the development of cancer of the skin, we are entirely devoid of an explanation for the growth of a malignant tumor high within the vault of the nasopharynx. A careful analysis of the histories of 40 patients who were the victims of malignant new growths in the nasopharynx, failed to reveal etiological factors of even the remotest significance.

While their cause remains a mystery, we have made clinical observations of much interest on their growth and behavior in the nasopharynx. It is a noteworthy fact that these neoplasms show a striking tendency to infiltrate upward, erode bone, and eventually disturb those structures which pass through the basal foramina. Lymphatic metastasis to the nodes of the posterior cervical chain occurs early in the progress of the disease, while extension by continuity of tissue is almost invariably toward the base of the skull. Seldom does one see such a lesion creeping downward along the lateral wall of the pharynx, and only in the very late stages of the disease is there sufficient forward extension to produce symptoms referable to the nose.

We have all seen the squamous cell carcinoma appear as a lesion no larger than a pea within the fossa of Rosenmüller and much to our amazement discover in a radiographic examination of the skull extensive destruction of the sphenoid and temporal bores. One usually finds, on palpation of the neck, a metastasis to the nodes of the posterior cervical chain at the time of the initial examination of the patient. Occasionally one observes that the lesion has taken its origin from the mucous membrane of the sphenoidal sinus and has caused early involvement of the abducens and optic nerves. Then, too, there is unusual

alveoli being separated by fibrous septa. The architecture of these growths was cystic and there appeared to be a tendency to form the reticulated structure of the adamantinoma. In one of the tumors, colloid was observed within the cystic spaces. In the other, there were duct-like structures with side branches suggestive of pituitary remains.

It is to be noted that in the embryological development of the hypophysis a stalk is formed which connects Rathke's pouch with the oral cavity. This stalk finally separated from the gland and epithelial remains is found in adult life somewhere between the sphenoid bone and the epithelial structures of the nasopharynx. This vestigial remnant of the epithelial tract, the pharyngeal hypophysis, forms the embryological anlage of the anterior pituitary lobe.

It seems quite proper to assume, therefore, that the two tumors before described, developed from the remnants of the hypophyseal duct and were, for that reason, teratological in origin and classified in that group of hypophyseal tumors to which the name "cranio-pharyngioma" has been given.

Tumors which have their origin in notochordal cells are occasionally found at the 2 extremities of the spinal column where the notochord is enclosed in the bodies of the

vertebrae and in the intervertebral discs. A group of 52 cases has been reported in the literature, of which number 12 were located in the region of the nasopharynx. Some developmental disturbance, or possibly trauma in later life, may liberate the notochordal cells from their investiture of the bone or cartilage. When thus liberated, they become free to proliferate and grow into tumors of large proportions. They are slowly infiltrating lesions of low malignancy, possessing an irresistible tendency to recur after operations which appeared to effect their complete removal. They are observed twice as often in males as in females and their presence is usually recognized during the middle years of life. Microscopically, the lesion is divided into lobules of various sizes by connective tissue strands and surrounded by a thick, fibrous capsule. Focal hemorrhages may arise from the small vessels within the trabeculae. The cells of the parenchyma vary with the degree of degeneration. In the younger parts of the lesion the individual cells are clearly differentiated and are observed to be round or polygonal, closely arranged, and of a distinctly epithelial character. The cells present varying degrees of vacuolation ranging from small cells with almost homogeneous cytoplasm, to large cells containing a nucleus and a surrounding ring of cytoplasm, with a group of vacuoles of very large size. In the older parts of the tumor the differentiation of the cells is impossible and

take the time to make a complete examination, or failed to give the proper interpretation to the symptomatology. A small lesion, developing within the office of the Eustachian tube and occurring in an individual with refractory throat reflexes, sometimes offers a most perplexing problem in diagnosis. Nevertheless, when signs and symptoms challenge a thorough examination of the nasopharynx, we must use all available means for inspecting this region adequately. Palpation, examination of the reflected image in the nasopharyngeal mirror, direct inspection through the nasopharyngoscope, and biopsy studies, when painstakingly and meticulously performed, will not fail to establish the presence or absence of a nasopharyngeal lesion in the vast majority of cases. In our series of 40 cases, the interval between the first symptoms and the diagnosis ranged from 1 month to 5 years. The average duration of symptoms before the diagnosis was made, was 15 months, and 10 of the 40 patients had been subjected to some type of operation for relief of symptoms before the correct diagnosis was established. Do not pass over, therefore, without careful scrutiny, those early signs and symptoms which point to neoplastic invasion of the nasopharynx.

We cannot review this subject without simple mention of that most interesting group of neoplasms which we classify as tumors of teratological origin. A variety of such lesions found in the nasopharynx are the result of congenital disturbances of development, or the misplacement of embryonal cells. In one instance, the new growth may develop from a mass of misplaced cells, in another, aberrant structures may undergo proliferation with the formation of a teratoma which may subsequently pass through the degenerative changes of malignancy. The etiological influence is vaguely referred to as some disturbance or irregularity of the mechanics of embryonic development.

In this connection, it is to be remembered that neoplasms of a malignant character may arise from developmental disturbances of epithelial tissue. In the nasopharynx for example, we may observe an adenocarcinoma originating in the region where squamous cell

epithelium alone is found in adult life. There can be but one explanation for such a phenomenon, namely, the excitation of columnar epithelium which was carried over as cell collections from the time of early embryonic growth. In the embryo, the nasopharynx is lined with columnar epithelium and some disturbance in the mechanics of development may cause it to persist until adult life. Subsequently these cells, remnants of embryonic growth, may undergo a wild proliferation and give rise to the pathological changes of an adenocarcinoma. In one of my patients, a female, aged 16 years, a tumor mass about the size of a hickory nut sprang from the vault of the nasopharynx. The lesion had been responsible for frequent epistaxis and a feeling of fullness and stuffiness in both ears. Biopsy demonstrated an adenocarcinoma with papilliferous alterations, obviously a lesion arising from columnar epithelium in a region which normally contains a squamous cell type in adult life. Such a new growth may give rise to considerable confusion concerning its histogenesis until one becomes familiar with the occurrence of bizarre neoplasms in many parts of the body, resulting from some irregularity in the processes of embryonic development.

In the past 22 years, 2 cases of a tumor of pituitary origin occurring in the nasopharynx have come to my attention. They are to be regarded as neoplasms of great rarity because a diligent search of the literature has failed to disclose a record of a tumor of similar nature. One occurred in a female, aged 40 years, who presented an enormous tumor in the posterior wall of the nasopharynx, causing symptoms referable to the ears and nose, the other was seen in a woman, aged 45 years, who gave a history of pain in the right eye and severe hemorrhages from the right side of the nose. The lesion was a soft, encapsulated tumor which filled the nasopharynx, protruded into the anterior nares, and produced a proptosis on the right side.

Both of these lesions presented similar pathological pictures consisting of soft, elastic tumors without capsules and showing a tendency to infiltrate the neighboring tissues. Both presented an alveolar grouping, the

HOARSENESS

FRANCIS E. LEJEUNE, M.D., New Orleans, Louisiana

FEW symptoms occur more frequently and are so universally disregarded as that disturbance of laryngeal function which we recognize as hoarseness. Hoarseness may well be defined as the danger signal of the larynx. Early recognition of the possible significance of this symptom may be responsible for the saving of many precious lives. Numerous conditions in their inception appear so trivial that little attention is given them. This is particularly true of hoarseness, because it occurs so frequently as a complication of a common cold, subsiding spontaneously, that little attention is given it. Any case of hoarseness lasting over a period of 2 weeks deserves and should have a thorough examination with the laryngeal mirror, for it is only by such a procedure that an early diagnosis can be made in cases of tuberculosis, syphilis, carcinoma, and tumors of the larynx. The importance of an early diagnosis cannot be stressed too vigorously as many of these conditions in their early stages are amenable to treatment. The presence of hoarseness does not always indicate the existence of a serious condition within the larynx. It does indicate, however, that the accurate approximation, equal tension, and synchronous vibration, which is so necessary for normal phonation, has been disturbed.

Jackson and Coates¹ enumerate over 60 causes producing hoarseness. Visualization of a few of these causes by means of color motion pictures affords an interesting study and creates a more lasting impression than it is possible to obtain by any other means.² Screen presentation of a large variety of such lesions is obviously advantageous, not only for the teaching of the student, but also for the benefit of the general practitioner into whose hands come most of these cases seeking relief. Not only should the general practitioner be made to appreciate the importance of voice changes, but the public at large should be made to realize that persistent hoarseness is the danger signal of the larynx. The general surgeon, over a period of years, has conducted a campaign of education in which women have been made to

realize the significance and seriousness of a lump in the breast. As a result of this campaign the mortality from cancer of the breast has decreased considerably. The laryngologists today are faced with the launching of a similar problem of education in which the public must be made to realize that persistent hoarseness is the danger signal of the larynx. It is the first symptom presented by intrinsic carcinoma of the larynx. The general practitioner and the public should be made to realize and appreciate the importance of voice changes. By waging a campaign of education we can make the public "voice conscious" and "hoarseness conscious." When this has been accomplished we may expect to see a large percentage of cases of carcinoma of the larynx in their early stages.

Hoarseness unaccompanied by pain, cough, or discomfort is frequently ignored by the patient and sometimes by the physician until more alarming symptoms appear. Regardless of how trivial hoarseness may seem, it should always be regarded as serious until proved otherwise, and the patient should always have the benefit of a laryngeal examination. As a rule a simple examination by means of a laryngeal mirror will be sufficient to establish a tentative diagnosis. Co-operation on the part of the patient is essential for successful examination and for this reason direct laryngoscopy is the method of choice when handling children. The suspension laryngoscope has given me such excellent results that I continue to use it in all cases in which direct laryngoscopy is indicated. It may be used under local or general anesthesia. My preference for the latter is responsible for the fact that the majority of my cases are given general anesthesia.

Probably the most frequent type of hoarseness seen both in adults and children is that produced by an acute laryngitis following a cold or an excessive use of the voice. Acute laryngitis with subglottic involvement is a rather common clinical picture in young children. This condition is better known to the laity as croup. This type of case readily responds to proper management. Diphtheria frequently produces dyspnea with accompanying hoarseness. This clinical picture is now seen less frequently since the introduction of toxoid as an immunizing agent. Among other conditions producing hoarseness in children we

Presented before the Clinical Congress of the American College of Surgeons, Chicago, October 25-29, 1937.

¹Jackson and Cortes. *Diseases of the Nose, Throat and Ear*.

²At this point a color motion picture film was presented showing pathological conditions within the larynx causing hoarseness.

the appearance is now that of a highly vacuolated syncytium

The treatment is surgical excision of the lesion, followed by some form of radiant energy. The prognosis, however, is very unfavorable for the spheno occipital group of chordomas and various reports in the medical literature show that the average length of life for the untreated cases is about $2\frac{1}{2}$ years from the time of identification of the lesion

TREATMENT OF MALIGNANT LESIONS OF THE NASOPHARYNX

My meager experience with 40 cases of malignant new growths of the nasopharynx leads me to conclude that treatment is exceedingly futile and the prognosis hopelessly discouraging. We have used radical excision, electrocoagulation, x ray and radium therapy in various combinations to meet the indications that appeared to be present and only one of the 40 patients is alive at the expiration of 2 years. This patient is the 10 year old girl to whom I have already referred who presented an adenocarcinoma of the nasopharynx which was classified as a lesion of teratological origin. The mortality among our typical cases of squamous cell carcinoma of the nasopharynx is 100 per cent and no therapeutic measures we employed seemed to combat satisfactorily the destructive influences of these lesions. Perhaps our discouraging results may be attributed, in part, to late diagnoses. It is true that most of our patients came to us 15 months following the initial signs and symptoms and demonstrated extensive invasion of the cranial bones. The gravity of such find-

ings is clearly understood. Nothing could offer a less sanguine prognosis than evidence of malignant infiltration of the osseous structures of the skull.

SUMMARY AND COMMENTS

1 The common malignant lesion of the nasopharynx is the squamous cell carcinoma. Tumors of teratological origin undergoing malignant alterations likewise may be found in this region.

2 Early diagnosis is dependent upon the recognition and proper interpretation of signs and symptoms which occasionally antedate the gross appearance of the lesion. In this connection, pain, cervical gland enlargements, and symptoms referable to the ear are to be given their true significance.

3 There is an irresistible tendency for neoplasms of the nasopharynx to extend upward and invade the base of the skull. Paralysis of cranial nerves thus occur, but they are late manifestations of the disease.

4 The diagnosis is frequently a most provoking problem because of one's failure to identify a small lesion in the fossa of Rosenmüller or for the reason that the neoplasm remains hidden within the Eustachian tube or beneath the surface epithelium of the nasopharynx.

5 All of the usual therapeutic measures for cancer have been advocated, but the prognosis remains hopelessly futile. There appears to be no adequate means of arresting its upward invasion with consequent involvement of osseous tissue. The deadly behavior of bone cancer is fully appreciated by all.

central origin frequently produce a paralysis of one or both vocal cords.

The most significant of all changes that may take place in the larynx is that produced by malignant growths. It has well been said that hoarseness is the danger signal of the larynx. Unfortunately, too few of the laity and the profession heed this danger signal. Few malignant lesions throughout the entire body present any earlier symptoms than intrinsic carcinoma of the larynx. The earliest manifestation of intrinsic carcinoma occurs on the vocal cords, usually at the junction of the anterior and middle thirds, producing at first only a slight alteration in voice. This represents the earliest form of intrinsic carcinoma which can be detected, and the first symptom presented is hoarseness. If this early warning symptom were accorded the recognition it deserves, many lives would be saved. It is generally agreed that 80 to 82 per cent of intrinsic carcinomas of the larynx respond favorably to treatment, yet the study of statistics shows that a very large percentage of these cases die from cancer of the larynx. The cause of this high mortality rate is the fact that an early diagnosis was not made. In recent years cancer has assumed a much higher mortality rate. From this we may conclude that malignant lesions are increasing or that our diagnostic methods have improved. It is certainly true that the laryngologists who are manifesting interest in cancer of the larynx are undoubtedly seeing more of these malignant conditions than in former years. One wonders whether this is a natural increase or the reward for years of work and interest manifested in this particular subject. It is deplorable, however, that such a large percentage of cases of carcinoma of the larynx referred to the laryngologist are so far advanced that little hope for a cure can be offered. The first symptom of intrinsic carcinoma is present early; the diagnosis presents little if any difficulty, and most important of all is the fact that this condition is curable in its early stages. Carcinomas occurring in other portions of the larynx aside from the vocal cords are as a rule not discovered early because they produce no alteration in voice function and no discomfort until the lesion is well advanced.

Concurrent with the diagnosis of carcinoma of the larynx must be the mode of handling such lesions so as better to effect a complete cure in as large a percentage of cases as possible. Obviously different stages of the growth will necessitate varying modes of attack. Briefly, those cases of incipient, intrinsic carcinoma consisting of an outcropping on the anterior or middle third of the

vocal cord respond most successfully to intra-laryngeal surgery. These are purely surface lesions confined to the vocal cord and could well be designated as cordal carcinomas. The tumor is small and there is no lagging or fixation of the cords. Suspension laryngoscopy permits one to remove and cauterize the base of these growths successfully. An excellent exposure of the laryngeal structures is obtained, and it is comparatively easy to remove these early growths by dissection followed by cauterization. When the growth has extended beyond the limits just described and two-thirds or more of the cord is involved, more extensive surgery will be necessary. As the growth extends in the long axis of the cord, there is an induration of the base and occasionally an early lagging of the cord is present. This is the type of case which demands thorough study and differentiation. Laryngofissure is the operation of choice and in properly selected cases the final results are most satisfactory. Border line cases are frequently seen which tax the diagnostic acumen of the surgeon. Persistent hoarseness over a period of time, gradually becoming worse, conveys to the mind a picture of an extensive lesion. Definite fixation of a cord with an extensive growth is a positive indication that conservative surgical procedures advocated heretofore will be of no avail. Radical surgery, such as laryngectomy, will offer some hope provided there has been no extension of the growth outside the laryngeal box. Conservatism when dealing with cases of carcinoma of the larynx must be disregarded and the surgery suited to the particular case instituted. I am convinced that when dealing with carcinoma of the larynx, it is better to err on the side of radicalism than conservatism.

While deep roentgen-ray therapy is now available and offers splendid results in some cases, the uncertainty of the outcome is such as to make me most skeptical. My cases receive one or two therapeutic doses of deep x-ray for fixation of the cells in mitosis just prior to operation. I am firmly convinced that surgery is the method of choice when dealing with carcinoma of the larynx, that x-ray therapy may be used as a valuable adjunct, and that these 2 methods should be used together when the occasion demands.

It is truly appalling to realize the large number of advanced cases of malignancies that are consulting the laryngologist for the first time. Too frequently these cases have progressed beyond the stage where surgical intervention will offer any hope of cure. Deep x-ray therapy can likewise offer little hope in these advanced cases. How are we to account for the delay of the patient

find thymic enlargements, foreign bodies, trauma, and, probably the greatest offender, papilloma of the larynx. The occurrence of multiple papilloma of the larynx in children is a most distressing condition. These growths are benign in character and may spring from any portion of the larynx. They are, however, frequently considered as malignant in so far as they recur repeatedly. I know of no condition occurring in that delicately arranged and highly organized voice box, with the possible exception of stenosis of the larynx, which requires more patience, perseverance, and careful surgery than do cases of multiple papilloma. In the removal of benign tumors great care and caution must be exercised not to injure or traumatize normal tissue. This is of the greatest importance when dealing with papilloma of the larynx because papilloma are autografting and will spring from any new raw surface created hence the necessity for the utmost care in the handling of these cases. Despite careful and painstaking removal of the growths, many cases recur repeatedly. I cannot as yet foretell when a patient is first seen whether or not the condition will respond promptly to treatment or whether repeated removals of the growth will be necessary in order to effect a cure.

The milder types of growth improve remarkably and after 2 or 3 roentgen ray exposures or the surgical removal of the growths the throat is free of papilloma. The other type comprises those cases in which every known method is used unsuccessfully to eradicate the growth. You can realize more clearly the obstinacy and persistence of recurrence of multiple papillomas when I tell you that 2 of my patients have baffled all attempts at eradication of the growth. One was first seen at the age of 4 with extensive multiple papilloma. Repeated removals of the growth were unsuccessful in preventing recurrences and extensions. At the age of 14 he developed multiple lung abscesses and died. At this time papilloma completely filled the laryngeal surface of the epiglottis, filled and overflowed the larynx, extended into the subglottic region and involved the trachea to within a short distance of the bifurcation. The other patient was first seen at the age of 3 with extensive papilloma which continued to recur as fast as removed. The early use of radium produced a stenosis of the esophagus. A second gastrostomy at the age of 20 was followed by complications and death. At this time the papillomatous mass was most extensive partially blocking the mouth of the esophagus, filling the larynx and protruding through the neck externally in the region of the larynx. Microscopical

examination of the growth showed a malignant degeneration of the papilloma. These 2 cases are briefly mentioned to show that all cases of papilloma do not clear up spontaneously at puberty. Some progress in spite of all efforts and even develop into malignancies.

Benign growths occurring in the larynx are responsible for alteration in vocal production. I have been fortunate in obtaining views of various growths occurring in the larynx such as vocal nodules, contact ulcers, single and multiple papilloma, hematomas, angiomas, fibromas, cysts, and granulomas, showing distinctly how they interfere with accurate approximation, thereby producing varying degrees of hoarseness. Benign lesions present the problem of accurate removal with as little trauma to normal tissue as possible. Delicacy in the handling of laryngeal tissue is amply repaid by little or no reaction following surgical removal of small tumors. The accurate and thorough removal of benign lesions practically assures no recurrence of the original growth except in those cases of multiple papilloma which recur repeatedly and may well be classified as potentially malignant.

Hoarseness as I have stated before, is nature's first signal of distress, and a laryngeal examination will give important information. Traumatism, foreign bodies, gumma, tumors of the thorax, aneurism, and enlarged thyroid glands may be productive of hoarseness. Occasionally a partial or complete paralysis of one vocal cord may be present, due to an enlarged thyroid, with practically no alteration of voice. In the event a thyroidectomy is contemplated in such a case, a pre operative examination may save the surgeon much embarrassment. For many years I have been associated with a service in a general hospital in which every patient subjected to thyroidectomy has a pre operative and postoperative examination of the larynx. The wisdom and value of such an examination are obvious.

In my experience tuberculosis of the larynx is always secondary to an infection in the pulmonary tract. The pulmonary process may not be sufficiently active to cause the patient any concern and the laryngeal involvement represents latent activity. Here early diagnosis is of vital importance.

The favorite site for tuberculous lesions of the larynx is within the interarytenoid space. Pain is a constant factor in advanced cases of tuberculous laryngitis. Syphilis may likewise affect the larynx in any of its various stages and often presents problems in the differential diagnosis, even to the laryngologist. Diseases of

Fig 1

Fig 2

Fig 2 Diagrammatic drawing of the position of the deciduous teeth buds and the germ centers of the permanent molars at 5 months

Fig 3

Fig 3 The influence of the development of the antrum on the rupture of the upper teeth. The shaded area is of an infantile superior maxilla with its antrum, which, as it develops, forces the permanent upper molar teeth into their normal position (Keith). When the normal antrum develops, the three molars are in contact with its floor.

The forcing of teeth, roots, or diseased bone into the antrum contaminates the sinus, which, as a rule, is already inflamed, with the result of producing an empyema. An acute antrum associated with a swelling of the cheek is suggestive of dental origin.

INCIDENT

Gordon Berry in two interesting reports read before the 1928 and 1929 meetings of the American Laryngological Association gave his impression of the frequency of the relationship between diseased teeth and maxillary sinusitis. His private cases showed 20 per cent of the acute and 80 per cent of the chronic maxillary sinus infections to be of dental origin.

In reviewing the case histories of 32 radical antrum operations done on our private patients during the past 16 months, 2 were the results of malignancies, 2 followed fractures obtained in automobile accidents, 7 had dental fistulas following extraction of teeth; 9 had chronic hypertrophic membranes or empyemas as a part of a pansinusitis; 12 of the antra contained 1 or more polyps of which 6 were considered of dental origin because of the site of their attachment. The other 6 cases of polypoidosis required bilateral antrum operations.

Infection of the sinuses in children is seldom of dental origin, the exception being the rare cases of osteomyelitis originating about the teeth of infants. In one such instance (Case 1), G. G., male, aged 4 months, was seen in consultation with Dr. E. C. Ellett for an or-

bitary cellulitis. A stab wound through the lower lid made by a surgeon in a neighboring town was unproductive of drainage. Examination and roentgenological study revealed an acute purulent maxillary sinusitis. At operation an osteomyelitis of the upper jaw was found and the child lost its 2 upper molar tooth buds. The older the patient under consideration with a maxillary sinusitis, the more likely will it be that dental infections play an important part as a causative factor.

DENTAL CYST

Dental cysts are more frequent than diagnosed, as they may present no characteristic sign or symptom and usually are accidentally encountered while raying the sinuses. If there is any suspicion of a dental cyst its presence can be proved by filling the antrum with a radiopaque oil and again roentgenographing the sinus.

a. *Radicular* (root, dental, or periodontal) cysts are the result of chronic inflammation of the periodontal membrane, usually associated with infected pulpless teeth. A typical example may be found about the upper lateral incisor, as the thickness of the cancellous bone in this region readily allows of cystic formation. All granulomas do not mature into cysts due to the lack of the cellular constituents essential to their development. These cysts may continue their growth after the removal of the offending tooth. They seldom cross the median line and their progress is outward,

in seeking medical aid in these advanced cases of malignancies? Can it be because the patient fails to realize the significance of persistent hoarseness, or has the general practitioner ignored the danger signal of the larynx? The importance of voice changes must be more fully appreciated and the

co-operation of the general practitioner solicited in an effort to direct these cases to competent laryngologists for examination and diagnosis. The importance of an early diagnosis must be stressed in all cases of hoarseness if we are to be successful in our fight against carcinoma of the larynx.

INFECTIONS OF THE PARANASAL SINUSES OF DENTAL ORIGIN

JOHN J. SHEA, M.D. F.A.C.S., Memphis, Tennessee

THE wonderful improvement in sinus patients following a clean up of their dental pathology is an indication of the close relationship between the infection of the paranasal sinuses and the teeth. The maxillary is the sinus most frequently infected by extension from the teeth. The ethmoidal cells can be infected secondarily by extension from the antrum, and in one of our cases a tooth was found within the ethmoidal labyrinth, acting as a foreign body. The frontal sinuses in turn may be blocked by the former sinuses and at times a slowly ascending purulent infection will produce a pansinusitis of one side from a dental infection. It is important in all cases of maxillary sinusitis that the teeth be carefully examined and studied roentgenologically.

There is a close relationship between the teeth and the maxillary sinus. The deciduous teeth have their nativity in the cancellous bone below the antrum, and at birth the bud of a deciduous molar is larger than the cavity of the antrum. At 5 months the bone behind the antrum contains the invisible germ centers of the permanent upper molars, one stacked upon the other. As the antrum pneumatizes, it extends backward and downward pushing before it the alveolar process containing the tooth buds. If the natural pneumatization of the antrum occurs, the upper molars are rotated into their normal position, the first at 6 years of age, the second at 12, and the third or wisdom teeth after the 18th year.

The antrum continues to increase in size throughout life, the increase in the latter years being due to the thinning of the bony walls. The exception to this natural law is when the development of the antrum is arrested during the formative period as the result of one severe infection or the accumulated action of repeated mild infections or allergy (vasomotor rhinitis and sinusitis), or when the removal of all the upper teeth allows a recession of the outer angle of the antrum due to the absorption of the alveolar process. Should pneumatization be excessive, the roots of the molars are more prominent within the antrum and the forward extension contacts the cuspid and rarely the incisors.

MAXILLARY SINUS

The maxillary sinus may be infected directly by either acute or chronic infections of the teeth immediately adjacent to the sinus or indirectly because of a lowered resistance as the result of dental infections. The direct extension occurs from periapical or periodontal disease, which produces within the sinus either an inflammatory reaction or a direct contamination. Dental insults account for a number of acute empyemas of the antrum, as when in doing an extraction a passage is made through an infected socket into the antrum. At times the incomplete hygiene of a socket will leave roots or decayed bone, which serves as an insidious focus, and as a starting point from which occurs an ascending infection. Traumatism may play a part and leave fractures through which infection may enter the sinus.

plastic procedures may be required for the repair of the surgical damage.

CUSPID AND INCISORS

When the pneumatization of the antrum is excessive, it will have a direct relationship with the upper cuspid, and in still rarer cases, the incisors. Periodontal infections about the upper cuspid and incisors will produce a swelling of the structures in the vestibule of the nose and an extension of an osteomyelitis may involve the septum.

CASE 3 A G was admitted to the Baptist Hospital in the middle of the night with an intense pain deep in the face. Two weeks previously he had experienced the removal of his upper teeth. The day after the extraction of the incisors, his upper lip began to swell and a throbbing pain developed within the nose, each night the pain demanded a sedative and on the night of admission, the pain became so severe that the medication was unsuccessful in relieving the suffering. The dental wounds were healing normally, but upon examination of the nose, the septum was found to be swollen. A roentgenological study revealed an increased density of the bony septum. Sulfanilamide treatment was begun and intranasal tampons were inserted every 4 hours for 20 minutes, during which time infra-red therapy was applied over the face. An abscess of the septum developed, which, on drainage, relieved the headache. The patient made an uneventful recovery.

ETHMOIDAL SINUS

Prolonged infection within the antrum will extend to the ethmoidal cells and in turn the blockage of the frontal duct by the anterior cells will produce a frontal sinusitis. Fortunately, early attention to the maxillary sinus disease will prevent the ethmoids and frontals from becoming chronic.

CASE 4 Recently a woman, L. B., aged 43, at operation had an undeveloped cuspid free within the anterior ethmoidal cells. This patient was first seen following an automobile accident at which time a deformity of the nose was corrected. Eighteen months later she returned with a history that she was not satisfied with a negative diagnosis as to the cause of a right sided headache, given her at one of our larger eastern hospitals. Examination and roentgenological study revealed a pansinusitis of the right side. Nasal treatments relieved the pain, especially if the right antrum were irrigated through the ostium. A radiopaque oil instilled into the antrum brought out in the roentgenological study that the membrane lining the antrum was uniformly thickened. An exploratory opening of this antrum discovered a diseased lining membrane, and after the agger nasi cell was opened, an undeveloped cuspid tooth was extracted. There is no way of ruling out that this tooth was not in its present location at the time of her accident, but the spacing of her teeth confirmed the opinion that the tooth had never migrated to its normal position. Studying the original roentgenogram made at the time of her accident, the shadow

Fig 4 Photomicrograph of a button biopsy demonstration of the pathology of the lining membrane in a case of an emptyema of the antrum of dental origin

eventually into the vestibule of the nose or the anterior end of the antrum. They grow slowly and with little pain and their presence is detected because of a bulging outward of the alveolar plate, the diagnosis being confirmed by a roentgenogram. These cysts must be differentiated from the median anterior maxillary cysts.

Treatment consists in the removal of the teeth bordering the cyst and surgical dissection of the cyst wall, the wound being allowed to heal openly by granulations. If the cyst has migrated into the antrum the latter should be opened and inspected. Should the antral membrane be diseased a radical operation is demanded but if the membrane appears healthy, a nasoantral window for drainage will be sufficient. I have watched the migration backward of a cyst from the region of the upper lateral incisor through the pyramidal process of the superior maxilla into the antrum. In its progress it devitalized the adjacent canine and first bicuspid.

b *Follicular cysts* (dentigerous) are less frequent than radicular cysts, being of develop-

mental origin, the result of proliferation and degeneration of the cells of the enamel organ connected with an unerupted tooth, the latter being included within the cyst. They occur at any age, but most frequently during the second dentition. The unerupted tooth, acting as a foreign body, stimulates the misplaced anlage to unlawful growth. The cuspids, incisors, and third molars are the most frequent offenders in either the upper or lower jaw. Histologically, they are surrounded by a fibrous capsule lined with squamous epithelium. The cyst consists of a cavity filled with a fluid and contains a part or the whole of a tooth. The teeth usually involved are permanent or supernumerary.

I have seen one follicular cyst in a child of 4 (Case 2), the condition being diagnosed as sarcoma of the superior maxilla but during an attempt to fill the antrum with a radiopaque oil, the cyst was entered and the oil replaced the contents of the cyst.

Because of their constant growth without pain, the condition is usually diagnosed as a tumor, the significant diagnostic point is the absence of a permanent tooth in the region of the swelling. A roentgenological study will confirm the diagnosis and the treatment is similar to the manner of handling a radicular cyst.

c *Adamantinoma* (multilocular) are rare benign tumors arising from dental epithelium. Histologically, they consist of irregular masses of epithelial cells surrounded by a fibrous stroma with a definite capsule. The tumor readily undergoes cystic degeneration, and the diagnosis is made because of the deformity produced, the absence of pain and signs of inflammation differentiate it from an active infection. At times the tumor may grow rapidly and by pressure destroy vital teeth.

The treatment is surgical and the larger tumors may leave deformities requiring plastic repair.

d *Dermoid cysts* are congenital accidents containing characteristically dermoid structures, such as hair, teeth, and the glands of the skin. Those found in the antrum originate in the hard palate and are diagnosed by their size and roentgenological peculiarities. Their treatment is surgical, and like adamantinoma

CASE 6 J. F. M. A dental surgeon misread a dental film and attempted to remove on the wrong side an unerupted upper third molar. The operation ended with a large opening through the posterior wall of the maxillary sinus and a strip of gauze packing was fitted into the wound. When the patient reported the next day, there was no gauze visible and an attempt to probe and irrigate the antrum for it was futile. There developed a pansinusitis of that side, which aggravated the old gentleman's arthritis. A radical antrum operation was necessary to remove the strip of gauze which was located high in the antrum.

CLOSURE OF DENTAL APERTURE INTO THE ANTRUM

The openings left after extractions vary from root size to massive injury. It is difficult to close a circular aperture the walls of which are bone, but if the canal made by the aperture is converted into a trough it will readily heal. This requires the removal of the outer wall of the canal and a sufficiency of the anterior wall of the antrum to allow the sliding down of a mucous flap, which is sutured in place with black silk. A removable dental appliance made with flanges is utilized to protect the healing wound until a permanent bridge is made.

FRACTURES OF THE MAXILLA INVOLVING THE TEETH

The sudden and permanent stopping of fast moving automobiles and aeroplanes throws the passengers forward with great force, striking their faces against protruding objects, usually on the dash board. The injuries sustained by the superior maxilla vary from simple, depressed fractures to crushing injuries in which all of the teeth contacting the sinus have been jammed into it. There is no set

rule of handling these accidents, but no teeth possessing attachments should be sacrificed at the emergency operation. The bony fragments of the hard palate and the walls of the antrum should be replaced and the teeth given mechanical support. Many will be saved and those lost will have served in preserving the contour of the alveolar process.

INTRA-ANTRAL TEETH

Unerupted teeth that migrate into the antrum will act as foreign bodies within the sinus, and should be removed.

CASE 7. C. W. R. sought relief from a chronic maxillary sinusitis. Roentgenological study showed the antrum involved contained 3 fully developed teeth within its cavity. The first molar had rotated its position and the crown faced upward into the antral cavity.

These intra-antral teeth sooner or later die and become foreign bodies and their removal is demanded.

FATAL COMPLICATIONS

An osteomyelitis of the superior maxilla following an extraction performed in the face of an active infection may prove fatal, either rapidly by causing a cavernous sinus thrombosis or insidiously as the result of a spreading osteomyelitis.

cast by the tooth was always behind the nasal process of the superior maxilla and could be read into the plate only with the foreknowledge of its presence.

MANAGEMENT OF ACCIDENTAL PERFORATION OF THE ANTRUM

When a tooth penetrates the antrum at its extraction, the socket and dental sinus should be thoroughly cleansed and left alone. A procedure of watchful waiting should be instituted, and if the antrum succumbs to the infection, the sinus should be opened through the nose. There is no excuse for tinkering with an antrum through an unnatural dental opening, and a dentist guilty of maintaining an alveolar opening into an antrum should be condemned. At times, a piece or a whole root will slip into the maxillary sinus during an extraction. When this occurs simple means should be tried to deliver it through the opening, but if simple measures fail, a window should be made through the anterior antral wall, and the foreign body removed. This is very simple when done by an experienced surgeon.

There is a tendency for the dentist to curette his perforation, and often an aperture remains which is so large that its closure requires a plastic operation.

The dentist is relieved of any liability of an antral infection, following a dental penetra-

Fig 9 Case 7 Roentgenogram demonstrating three molar teeth within the antrum and one at the angle of the lower jaw.

tion, if he immediately refers the patient to a competent rhinologist, and does not interfere with the antrum. The question of legal liability is solved, for the patient cannot successfully sue the dentist for penetrating the antrum, but if the dentist continues to treat him he (the dentist) may be liable for not doing what "the state of the art" demands. I once recovered from an antrum a piece of wooden applicator broken off in the antrum in an attempt by a doctor to replace a polyp protruding through a dental opening. Fortunately, the same individual was the patient and the doctor.

CASE 5 W L R Dr Justin D Towner while removing the first upper molar discovered that the anterior buccal root penetrated into the antrum. He immediately referred the patient and upon examination and roentgenological study the antrum was found to be infected with the ostium closed which accounted for the absence of nasal discharge. Two years previously a radical antrum operation was performed on the other antrum of this gentleman because of a neglected nasal condition following a similar dental complication. An antral nasal window was made into which a No. 16 F rubber catheter was inserted as a drain. The discharge was very offensive and to clear the antrum permanganate potash 1:4000 solution was instilled through the tube into the antrum frequently for 2 days. Under this treatment the fistula healed and the patient escaped the fate of his former experience.

DANGERS OF PACKING A DENTAL FISTULA

When a dentist penetrates an antrum he should avoid extensive curetting of the fistula tract and above all never insert any packing capable of slipping into the antrum.

There has, however, in this brief span of years been an astonishing advance in the requirements for admission to schools and their number has been reduced from 162 to 67 approved four to six year schools. It is generally recognized that "the undergraduate course of study can only begin the education of the physician, for he must remain a student all his life" if he is properly to fulfil his obligations

"A widespread and permanent improvement in the quality of medical service cannot be secured until graduate medical education has been developed at least to the level of excellence of the better undergraduate courses."

This desideratum is being approached in certain of the specialties which have organized national boards to establish the qualifications of the individual to practice a specialty and to make public those so qualified. Such a board in surgery has been established. We may justly hope that it will do much to improve the situation. If present plans mature the College will be in a position to give invaluable co-operation.

This scheme is in keeping with an objective long held by the College. Indirectly, it will as time goes on improve the professional attainments of our fellowship for in most cases it will constitute a hurdle which the aspirant will have taken successfully before entrance into the College. But it is not proposed that the College shall in any sense abrogate its right to determine the fitness of the candidates for its own membership. Special consideration must be given to attributes difficult to ascertain by the methods so far set up by these Boards, such as judgment, integrity, and personal fitness.

The American Board of Surgery representing the various surgical organizations of the country proposes to initiate or expand in numerous properly equipped hospitals the training for several years of the graduate student under intimate control and instruction. This would constitute an apprentice type of experience and should embrace the fundamental sciences of anatomy, physiology, pathology, as well as the history of surgery.

The College has gone on record as whole heartedly supporting this enterprise. A Committee on the Graduate Training for Surgery

appointed by the Board of Regents reported in October, 1935. This whole question is so important and is so little understood that it seems well to summarize this report which has contributed to important developments in surgical education.

The discussion was confined to the period in the development of a surgeon between the acquisition of his medical degree and his qualification as a surgeon; this may be termed the graduate phase as distinguished from the undergraduate and postgraduate. It was felt that intensive training involving much actual experience and responsibility and further study in anatomy, physiology, and pathology as related to surgery would most satisfactorily lead to the development of qualified surgeons. The required opportunities and facilities for such training exist only in a very limited number of teaching hospitals associated with schools of medicine. It was, therefore, recommended that non-teaching hospitals with proper personnel, plant, and organization be encouraged to undertake graduate training for surgery and that the College establish a minimum standard requisite for the approval by the College of such hospitals for training surgeons.

The report was approved and the committee was authorized to co-operate with committees of other surgical organizations in the development of a program in accordance with the tenor of this report.

But even when the young man with the background and training prescribed by the Board of Surgery launches upon his own, he cannot be considered a perfected product.

"In this broad earth of ours,
Amid the measureless grossness and the slag,
Enclosed and safe within its central heart,
Nestles the seed perfection."

Walt Whitman

Much in years and labor is required to smelt the slag and to free the seed of perfection from its enveloping husk of measureless grossness.

Hippocrates realized this in stating poetically, "Such, in effect, as is the culture of plants, is the study of medicine. Our natural disposition is the soil; the precepts of our masters are the seed; instruction, begun from

THE 1937 CLINICAL CONGRESS

THE COLLEGE AND THE CULTURAL ASPECTS OF SURGERY

EUGENE H. POOL, M.D., F.A.C.S., New York, New York

ON November 15, 1912, it was voted that a College of Surgeons be organized. Peculiar significance, therefore, attaches itself to this meeting by reason of the fact that it is the quarter century mark in the history of this College.

The general objective of its founders was the elevation of the standard of surgery by means of the following specific measures:

1. Development of a comprehensive association to enable visiting surgeons to see surgical confreres at work and to discuss with them problems of practical surgery.

2. Enrollment of competent and ethical surgeons.

3. Opposition to the barter in patients by fee splitting.

4. Protection of the public from incompetent, dishonest and unnecessary surgery.

5. Improvement of hospitals and teaching institutions.

Notable progress has been made toward these goals. But it has not always been smooth going. There have been stumblings and uncertainties, criticisms and contests. Yet the College has survived and now holds an important place in and exerts a salutary influence upon American surgery. Its accomplishments and activities need not be reviewed save in so far as they suggest questions of policy for the present and future.

Surgical education looms up as the most important problem at the present time. In analyzing it we find four phases:

1. The making of the man.

2. The making of the doctor—undergraduate education.

3. His training and qualifications for specialization in surgery—graduate training.

4. The final step in the making of a surgeon—postgraduate study.

Address of the Returning President presented before the Clinical Congress of the American College of Surgeons, Chicago, October 25-29, 1937.

Let us keep these phases in mind during our discussion.

Cutler states that "the real education of the surgeon is a postgraduate affair." But this is true only in part. It overlooks the all important period of development which I have called "the making of the man." The importance of this has been appreciated throughout the ages. To quote Horace, "A cask will long retain the flavor with which, when new, it was impregnated." And Kipling epitomizes the thought in opening his autobiography: "Give me the first six years of a child's life," he says, "and you can have the rest." It is the early formative years that have the greatest influence upon character formation.

That something is wrong with our system of education is emphasized by the words of notable contemporaneous educators. Sir Alfred T. Davies says, "We have so systematized our education that it has lost its soul. Intellectual curiosity has been destroyed and independence of character has been sacrificed for cleverness." And President Butler writes, "We must get rid of the notion that education is identical with instruction and that preparation for making a living is on the same plane as preparation for life."

We shall, however, pass over these inferences and direct our thoughts to medical education with special emphasis upon the preparation and qualifications to practice surgery. Thirty-five years ago "only 20 states had any requirements of general education whatever and only 10 of these required graduation from a high school. No state demanded any college training preliminary to the medical course which in many schools at that time was only three years in length."

A man with such meager preparation was legally entitled to undertake major surgery.

Wills, J. C. R. *People's Current trend in medical education*. New York: State J. Med. 1935; 30: 1930-1942.

Among our 12,000 members mistakes have been made. This is past history. It takes time to develop a plan of certification. This is still being developed and each year the procedure is becoming more and more efficient. I venture to predict that in a very few years the decisions of the Credentials Committees throughout the land will meet with universal approval. Let me in this connection call to your attention a recent ruling in regard to the requirements for fellowship in the College.

Applicants for fellowship whose qualifying medical degree shall have been obtained after the date of January 1, 1938, shall be required to present evidence of having completed three years of hospital service in one or more hospitals approved by the American College of Surgeons for graduate training in surgery, of which two years shall have been spent in training in surgery. In the case of graduates of medical schools which withhold the medical degree until after a fifth year of hospital internship, the date set will be January 1, 1939.

In the development of modern surgery technical aspects progressed by notable stages. Speed was at first exploited. James R. Wood¹ effected a thigh amputation in 9 seconds. Then came the anatomical era, represented by such men as Frank Hartley. Each structure was carefully and laboriously outlined by sharp dissection. Halsted's example of prolonged meticulous dissection, careful asepsis and thorough hemostasis probably made the greatest impression on the surgery of today. Technique is now relatively standardized in two schools: one, silk and slow; one, absorbable material and measurable speed. Both insist upon the essential features, careful sharp dissection, hemostasis, asepsis and the minimum of irritating foreign bodies. It is no longer the technical but the mental supremacy that makes the great surgeon. It is the head, not the hand. Besides those general qualities which we have outlined, the competent surgeon must, besides clinical experience, have knowledge of pathology, physiology, general medicine, and psychiatry. Centuries ago it was said, "Only he who in himself unites medicine and surgery is a perfect physician."

The physician who knows only one branch is like a bird with only one wing." As to psychiatry, Bard remarked over 100 years ago, "The physician who confines his attention to the body knows not the extent of his art. If he knows not how to soothe the irritation of a troubled and enfeebled mind, to calm the fretfulness of impatience, to rouse the courage of the timid, and even to quiet the compunctions of an over-tender conscience, it will very much confine the efficacy of his prescriptions; and these he cannot do, without he gain the confidence, esteem and even the love of his patients."

Culture and industry and constant study are essential. Rappleye tersely and idealistically summarizes the motives of our present education. "After all," he says, "the purpose of a medical training, broadly conceived, is to prepare a cultured and educated gentleman and not merely a technician."

To return to common sense; one must treat the patient, not the disease.

Can anything be more ill advised than to tell a 75 year old clergyman, whose only pleasure is smoking, that he must give it up because a small patch of leucoplacia may develop into cancer? This was done by an eminent specialist. The patient was advised otherwise and is still smoking at the age of 85.

Or can anything be more foolish than a six hour operation for advanced carcinoma of the breast on a woman of 79? In such instances the surgeon follows a rule of thumb method and does not consider the interest of the patient. He fails to grasp the all important axiom of Hippocrates, "to do good and to do no harm."

Suggestions are heard that something should be done to meet the urge of the medical man for a participation in the surgeon's fee. In other words a compromise. One reads, "First, the economic maladjustment in medicine makes it imperative for the man in general practice to indulge in fee splitting or else it would not be as prevalent as it is. Second, organized medicine will never get anywhere by condemning the practice but must offer something constructive in its place." There should no more be a compromise in regard to this, than there should be a compromise with

¹Bradshaw, J. H., James Rushmore Wood. Surg., Gynec. & Obst., 1929, 48: 447.

childhood, is the sowing of the seed in proper season, the place where instruction is given is the surrounding air where the plants find their nourishment, diligent study is the hand of the workman, finally, time strengthens and brings all to maturity."

Graduate study must continue throughout life. In the past, opportunity for this has been largely restricted to foreign lands.

Even centuries ago students journeyed to Bologna, Padua, and Salerno. Through Lanfranchi the Italian influence was injected into France. It was even then taught that "no one can be a good physician who knows nothing of surgical operations, and no one can operate who does not know medicine." It was through the universities at this period that the teaching of medicine was systematized and received its stimulus toward modern efficiency and graduate opportunity. During much of the 19th century English and Scotch students went to Paris, but later to Berlin and Vienna, which offered rich hospital and laboratory facilities. Our forebears, beginning with Morton and Bard, received their inspiration largely in the mentioned foreign centers.

But the child has grown apace and surgery in America is now on a plane so high that we are no longer dependent to an appreciable degree upon outside resources for purposes of surgical training. Indeed the tide has turned and students from afar are coming to us in progressively increasing numbers. Technical developments and influences from all sources have been garnered and culled in the clinics of our country and the simplified net results have been transmitted to the individual surgeons throughout the land. There is now no excuse for a man who has had opportunity to do a reasonable amount of surgery to do poor surgery. In his early years, however, he may well be a menace if left to his own devices, uncontrolled and without supervision. A large number, moreover, will always be mediocre, merely technicians. How he can be controlled and how more men can be lifted above mediocrity are problems for this College.

What is it that makes the great surgeon? To answer this one naturally attempts to analyze the characteristics of the masters

with whom he has come in contact rather than those who have been analyzed and dissected by others. The outstanding and invariable quality has been that uncommon virtue termed common sense. Bull, Peck, McBurney, Richardson, Judd, to mention a few only, had a certain something best termed a nice judgment. This quality is a gift from God and such men would probably have been equally competent in other walks of life. Such a man rarely gets himself or his patient into avoidable trouble and rarely makes unwise decisions.

Humanity and kindness come next, which lead such men to think primarily and dominantly of their patient's welfare. John Hunter had these qualities to a supreme degree. Common sense, modesty, kindness and charity. Crabtree states "His works were simply announced as by John Hunter. A plain door plate, with the same name, announced his residence. Money was a secondary consideration to him. To a poor tradesman from whom he had received 20 guineas for performing a surgical operation upon his wife, he returned 19 guineas, having learned with what difficulty and extreme self denial the husband had raised the money. 'I sent back 10 guineas and kept the 20th,' he said, in apology for retaining even the one, that they might not be hurt with an idea of too great an obligation."

Next, resourcefulness and courage but never rashness that is, the ability to meet without loss of nerve unexpected and serious conditions sometimes of his own making.

Technical skill and a scientific training are a *sine qua non* but are inadequate without the above attributes. Technique allows skillful routine work but alone it marks the artisan, not the surgeon.

These traits cannot be taught, they are God given.

Since the College cannot altogether change the type of man, extreme care must be taken to exclude the incompetent and the male factor and to admit only those of ability and sterling character. "Only men who have given proof of their competency should be entitled to public recognition and trust as surgeons."

NOTES ON 1937 MEETING

BOWMAN C. CROWELL, M.D., Chicago, Illinois

THE annual Clinical Congress ranks among the major educational activities of the American College of Surgeons, and the 1937 Congress in Chicago had the most able form of assistance from the Chicago surgeons in providing a worthy educational program in clinical surgery. Under the guidance of Drs. Vernon C. David and Michael L. Mason, a much appreciated reorganization of the arrangement of the surgical clinics was instituted so that a continuous clinical program in general surgery and each of the surgical specialties was provided. This arrangement made it possible for each Fellow in attendance at the Congress readily to find worthwhile clinics in the subjects of his special interest on each day. Overcrowding of the clinics was in a large degree obviated by precautions which had been taken by the committee on arrangements in cooperation with the hospital administrators.

The scientific meetings in general surgery and surgery of the eye, ear, nose and throat, which were held in the afternoons and evenings at headquarters, supplemented the purely clinical programs in the hospitals and covered many subjects of current surgical interest. The symposia on the subjects of cancer, fractures, and traumatic surgery continued to hold the interest of the audiences, and the attendance served to illustrate the great current importance generally attached to these subjects to which committees of the College are devoting much time and constructive effort. The reports furnished by these committees reflected a satisfactory progress in their work.

A symposium on graduate training for surgery, participated in by representatives of other organizations, served to emphasize the importance of such special training for surgeons and to crystallize the present trend of organization for such a purpose. It is expected that more and more hospitals will organize their work and otherwise equip themselves so that an increasing number of residencies for

graduate training in surgery may be available.

At this Congress the Presidential Meeting and Convocation were combined on the evening of the first day. Following the installation of the new officers, the approved candidates were accepted into fellowship and thus were able to attend the other meetings of the Congress as Fellows. These candidates had assembled at College headquarters during the afternoon where a recapitulation of College activities and the significance of active fellowship were presented by officers of the College. This assembly was followed by a social hour during which an opportunity was furnished for the candidates and their families to become familiar with the home of their College.

Another series of meetings was held at College headquarters on Wednesday morning when there were assembled the Judiciary, Credentials, and local Executive Committees. Officers of the College explained the functions of these committees, and an informal discussion of their duties and responsibilities ensued in the course of which methods for accomplishment of their purposes were elucidated. The beneficial effects of these assemblies were the subject of much favorable comment by Fellows during and after the Congress.

The almost continuous projection of motion pictures on surgical subjects was a feature of the Congress that attracted large audiences and again emphasized the educational advantage of this medium. Preliminary review at the College of all films shown at Congresses serves to insure a high type of motion picture programs and these seem to be appreciated if the volume of the attendance can be taken as an index of real interest.

No review of a Clinical Congress would be complete without mention of the important conferences and demonstrations on Hospital Standardization, but these are being reviewed separately.

Lay education on medical and hospital subjects was carried on during the meeting

the man who kidnaps a child. The professional abortionist is less objectionable, to my mind, than the man who splits fees. While he is breaking his Hippocratic oath, he at least is doing something which he conceives to be right and for the welfare of the patient.

To the fee splitter may be applied the words of Hippocrates, "So false a judgment seems to me to depend principally upon this—that the profession of medicine is the only one that is subject to no restriction or punishment, except disgrace, now, disgrace does not wound those who live by it."

The College is taking active and aggressive measures to eliminate the fee splitter and to clean up hospitals which are nests for these vultures.

Its Judiciary Committees and the Board of Regents have been particularly active during recent years in investigating and penalizing hospitals and individuals who have been found guilty of fee splitting and other breaches of ethics. There is a Judiciary Committee for every state and province, to which all questions of personal ethics dealing with Fellows of the College are submitted for investigation and report to the Regents. The mere knowledge of the existence of such a committee, with power to investigate and make recommendation, has had a very salutary effect in regulating local situations, and the plan in operation enables the College to act intelligently in dealing with undesirable Fellows, or situations which involve candidates or institutions.

The Clinical Congresses have become so successful that the clinics are often not able to accommodate the number who wish to attend. The Sectional Meetings which are miniature Clinical Congresses, five of which are held each year, will probably relieve this embarrassing situation.

Probably no activity of the College has been more effective and more productive of results than hospital standardization. It is distinctly an educational project and has affected profoundly the members of the hos-

pital staffs. If the plans of the Board of Surgery materialize, such standardization will be an essential link in the chain.

We have discussed the five points which were enumerated as the purposes of the founders of this College. At this quarter century mark are there not other objectives to which the energies and resources of the College might be directed?

The historical aspects of surgery call for clear definition and statement. The College, through its Fellows and as an organization, should bring its influence to bear upon the young aspirants in surgery. It is a fault common to many organizations of "higher learning" that they more largely affect those who have "arrived" than those who are "on the way." The student in surgery, undergraduate as well as graduate, should be taught the history as well as the techniques, et cetera, of surgical practice. The College, by means of fellowships, prizes and awards, might well encourage the pursuit of the cultural aspects of surgery among the younger men.

The College is qualified to serve in the crystallization and guardianship of the highest and best traditions in surgery, which call for a continuous reiteration and restatement of the ideals of surgery and of the surgeon. In this commercial age it is especially important that conscious efforts be made to encourage ideals, develop character, and support the highest professional standards. I have read the addresses of our former presidents and am much impressed not only by the number of distinguished men who have occupied this office but by the high ideals expressed by them as to the functions and future of this College. To be included in the list is an honor for which I thank you. I realize how inadequately I have filled the office. One is bound to make comparison with such a one as our late and much lamented president, Robert Greenough, who labored for the College with such sound and impartial judgment that he will ever live in its history as a shining inspiration and outstanding example.

TWENTY YEARS OF HOSPITAL STANDARDIZATION

MALCOLM T. MacEACHERN, M.D., Chicago, Illinois

THE Twentieth Annual Hospital Standardization Conference held in Chicago in connection with the Clinical Congress of the American College of Surgeons demonstrated a sustained interest in the hospital program which has been carried on by the College during the past twenty years

The addresses, papers, discussions, and demonstrations were highly interesting and instructive. There were two especially significant aspects of the meeting. One of these was the participation in the program by representatives from other leading national medical and hospital associations—the American Medical Association, the American Hospital Association, the American College of Physicians, the Canadian Medical Association, and the American College of Hospital Administrators. Each of these organizations has its special interest in the administrative, educational, or professional functions of the hospital. All of these subjects are embraced in the comprehensive program of the College which is concerned with continuing improvement in the institutional care of the sick and injured.

The other outstanding evidence of individual and group interest in a common problem was the intimate discussion of hospital service in conferences in which physicians, trustees, hospital executives and personnel were jointly concerned. It augurs well for the future care of the sick when the interests of various individuals and organized groups can be harmonized in this manner, thus giving greater momentum to the endeavor to promote better care of the patient.

There was the customary interest in the announcement of the list of approved hospitals for 1937, based on the twentieth annual survey. Twenty years ago, in 1918, only 89 hospitals merited approval by the College. This year 2,621 hospitals were awarded full or provisional approval. While the increase in the number of approved hospitals in the last decade has not been spectacular, it has been

steady and substantial. Actually, the progress of this work cannot be measured by the number of new hospitals added to the approved list, but rather by the raising of the entire level of hospital service. Once a hospital meets the Minimum Standard for Hospitals, it is expected to press forward to ever higher attainments. It can be said of Hospital Standardization that it is far from static in its influence, since hospitals approved years ago continue to show notable advances from year to year, and the rate of progress is accelerated by the growing appreciation of the advantages of united effort under this program.

Because of the emphasis which is being given to professional education as it affects the hospital personnel today, a number of discussions in the hospital conferences were devoted to this subject. Nurses, medical social workers, dietitians, technicians, and medical record librarians must meet definite standards of education and training in order to maintain present-day standards of service. The medical staff is involved in the trend toward stricter basic standards of preparation for all services of the hospital which are related to diagnosis and therapy.

Graduate training for general surgery and the surgical specialties, as well as for medicine and the medical specialties is, therefore, a live topic today. It was agreed at the conference that the facilities of non-university connected hospitals would have to be utilized to provide the necessary further opportunities for graduate training. The surgical staffs of many hospitals are already taking active steps to establish definite standards of qualifications for those who wish to do major surgery. In one large city where there are a number of approved hospitals a definite standard for major surgery has been agreed upon. This is a trend in the right direction, but training and experience should be the basic consideration. Every well organized, approved hospital, with adequate personnel and facilities, should actively support any legitimate move to promote

through the press and radio and at a community health meeting. The co operation of the representatives of the press and radio with the local committee on public relations was cordial and effective.

The scientific and technical exhibits reached a proportion not previously attained by the Congress, and each served a valuable educational purpose.

Scientific exhibits which were prepared by the College were supplemented by those of individuals and of other national organizations which are engaged in work which has a direct bearing on the work of the College in its Departments of Hospital Standardization and Clinical Research. Many of the technical

exhibits demonstrated the modern trend of such exhibits in presenting material of a direct educational nature.

Each year more and more surgeons from foreign shores are paying American surgery the compliment of attendance at our Clinical Congresses and this year the list of foreign visitors was a long and distinguished one. An honorary fellowship was conferred upon Mr. J. P. Lockhart Mummery of London who delivered the annual oration on surgery on the subject "The Surgeon as a Biologist."

Chicago surgeons and hospitals are to be congratulated on the excellent program provided and they merit the thanks of the American surgical profession.

OBSTETRICS AND GYNECOLOGY

RADICAL OBSTETRICS AND NATIONAL MATERNAL MORTALITY

FRANK W. LYNCH, M D., F.A.C.S., San Francisco, California

THE practice of medicine has undergone remarkable changes in recent years. Discoveries in biochemistry and other fundamental sciences have broadened our understanding of disease. Improved methods of anesthesia and operative technique have opened up new fields for surgery and have caused drastic changes in treatment of many diseases. Naturally there have been developed strongly conservative and radical schools. Yet in no branch of medicine are the two schools farther apart in indications for surgical treatment than they are in obstetrics today. The ultraconservative view that the average labor could be entrusted to an experienced nurse or midwife as is done in many countries has never been favored here either by our women or by physicians, even though the latter undertook the prenatal care, repaired the lacerations, and took care of the complications which ensued. Rightly or wrongly, there is a gradual elimination of the midwife in nearly all sections of the country.

On the other hand, the radical school feels that childbirth in the hands of nature is too crude to fit in with the ideas of modern life. Led by a small but active group of well trained obstetricians, they are doing what they can to alter it. Much surgery has followed in consequence, and we are in the midst of a furor of operative obstetrics. A number of different groups of physicians have been attracted to the movement. All of them have surgical aspirations but few of them have had much practical experience in obstetrics. As a group they see the new movement chiefly as a new field for surgery. Indeed some of them limit their obstetric practice to patients whom they themselves select for cesarean section. On the other hand, there is a large group of experienced practitioners who are becoming more radical, not because of convictions but because they find it both expensive and foolish to swim against the tide.

While many reasons are given for this radical movement, the most important one is woman's

insistence for childbirth without pain. Brought up from infancy on the lay propaganda of twilight sleep, and with the achievements of modern medicine spread before her almost daily in the lay press, she reasons logically from the evidence put before her by untrained lay women that, in this day of scientific medicine and surgery, the risk in childbirth must be trivial indeed. She cannot be blamed for accepting unhesitatingly any method of delivery which promises a living child and which is conducted under anesthesia or deep analgesia.

The modern school of radicalism in obstetrics started with effort to restrict pain, because it has been known for ages that man cannot improve a labor which is progressing normally except to reduce pain. With the routine use of analgesia and anesthesia for the entire period of labor came an unusual amount of uterine inertia requiring operative interference. Then followed attempts to shorten labor by instrumental or operative delivery under anesthesia. Untrained men soon learned that mid-forceps, high forceps, and version can be very difficult operations with very sharp and narrow indications and definite contra-indications and that primary cesarean section is much easier for them to perform. As a result, in various parts of the country today, labors are precipitated by the artificial rupture of the membranes, conducted under heavy analgesia and anesthesia, terminated by low forceps, version, or cesarean section almost as routine.

This is not the time to argue the theoretic merits or demerits of marked radicalism in obstetrics, nor to review the credo of those who see pregnancy as a 9 month disease, nor to discuss whether labor is a normal or abnormal process because it is attended by severe pain, tearing of tissues, and the death of thousands of women and their infants each year, nor to comment on the fact that in these days of wars, strikes, unemployment, and high taxes the arguments aforementioned for radicalism seem trivial indeed. Nature in the raw is seldom kind. There were 12,544 maternal deaths in the United States in 1935. Yet, ten thousand persons were killed last year by homicide. Eight times more people will be killed by automobiles

Presented in the Symposium on Obstetrics and Gynecology before the Clinical Congress of the American College of Surgeons, Chicago, October 25-29, 1937

graduate training in general surgery and the surgical specialties

A notable feature of the hospital standardization program this year was the attention given to the departments within the hospital which are related to oral surgery, psychiatry, physical therapy, pharmacy, medical social service, and others. The discussions emphasized the need for good organization and efficient supervision and control of these services which are so closely related to the rapidly advancing interest in improved methods of diagnosis and therapy.

Medical staff conferences received a due share of attention, it being generally believed that although frequently medical staff conferences are far from ideal, because of the sensitiveness displayed by some staff members, nevertheless this important practice in approved hospitals has been rapidly improving both in frequency and in quality of the discussions. Approximately 50,000 medical staff conferences were held in 1937 as compared with a possible 5,000 twenty years ago.

To a small degree this provides an estimate of the great benefits which are conferred both upon the patients and the members of the medical staff through the wider acceptance of such conferences, the success of which naturally depends upon positive and enthusiastic leadership. The conduct of the medical staff conference formed the basis of a demonstration at one of the sessions.

The hospital conference revealed that in many instances, the making and keeping of medical records is still a weak point in hospital work although in general a great advance is noted. Medical staffs would do well to evaluate the quality of their medical records through frequent tests of usage for group

studies and the writing of papers. The late Dr. John B. Murphy kept excellent medical records. He asserted that, given a record which was properly written and of good quality, in ninety cases out of a hundred a reasonably accurate diagnosis of the disease or condition could be made without seeing the patient. Complete medical records reflect the scientific spirit of the medical staff, the care and precision with which they do their work, the progressiveness of the medical profession of the community, and the sincerity of purpose of the institution as a whole.

Emphasis was placed upon the desirability of achieving the objective, "an accredited pathologist for every approved hospital," and the importance of continued progress in the practice of radiological diagnosis and therapy. In the latter field the disturbance over economic status should not be permitted to retard the advancement of this science.

All of the discussions in this year's hospital standardization conference appeared to culminate in one idea which in the past was not always emphasized: the patient must not be regarded merely as an organism with a heart, lungs, kidneys and other vital organs, without due recognition of the fact that he is a human being and not a number, and that he has a distinct personality and many idiosyncrasies. The new idea in hospital service is to treat the patient as a whole and to recognize the interrelation of physical organs and functions and the inseparability of these from the patient's mental and emotional characteristics. It is an exceedingly serious responsibility that the modern hospital must assume if it is to measure up to its full possibilities in the advancement of medical science and in its service to humanity.

Fig. 3 Trend of maternal mortality in Massachusetts

graduate instruction The American College of Surgeons has done a great service by insisting upon staff meetings, mortality studies, proper diagnostic equipment, separate units for maternity cases, and consultation for obstetric complications in hospitals which it certifies. The problem cannot be solved by such means, however, because of the large number of hospitals which will always fall short of the requirements for certification and never come under the definite control of any of our present medical organizations. Yet these hospitals will continue to admit obstetric cases.

The Federal Government through its Children's Bureau is acting with the various state boards of health to enable our medical organizations to give refresher courses to practitioners in their local communities. Courses of this type, however, can never be other than elemental nor accomplish more than to help develop a proper background. The formation of the American Board of Obstetrics has done much to create interest in more extensive obstetrical training. While these various movements sometime will make it difficult for the untrained obstetrician to practice radical obstetrics with the approval of his fellow physicians, it may take many years before this desired result will be attained. What is urgently needed at present are more institutions in which the young graduate can work as an apprentice and receive adequate practical instruction.

Medical schools can never be expected to train all of their students as surgeons or obstetricians. They are equipped to give only the groundwork of any branch of medicine. It is true that undergraduate obstetric education is constantly improving. The teaching of obstetrics and gynecology by the same instructors has marked a great advance. Yet no amount of classwork, laboratory courses, moving pictures of operation, and manikin exercises can train the student to pass directly from the classroom to care for other than a perfectly normal obstetric case. After the theory must come much apprentice work before the student learns judgment and technical skill. Yet

Fig. 4. Trend of maternal mortality in Pennsylvania

Fig. 5 Trend of maternal mortality in Ohio

(These graphs were compiled from material furnished by the Children's Bureau of the United States Department of Labor.)

state boards of medical examiners do not demand evidence of adequate practical training as prerequisite for their examinations.

There are very few institutions in America where a young graduate can receive even one year's training—the minimum time in which one may obtain a working knowledge of obstetrics provided, of course, that there is adequate instruction and supervision. The *Journal of the American Medical Association* lists but 82 approved hospitals admitting more than 1,000 patients annually which offer residencies in obstetrics or obstetrics and gynecology. Only 62 of this number offer both resident and assistant resident positions. Altogether there are only 287 positions listed which offer a minimum of even one year's experience in obstetrics, including all approved hospitals, even those with less than 1,000 admissions per annum. When we reflect that approximately 5,000 students graduate yearly in medicine, we see that few of them can receive obstetric training. Comparatively few students can obtain even the sketchy obstetric training given in a rotating hospital service of a month or two of obstetrics or in the three or four months of home delivery service. Yet this lack of practical experience prevents comparatively few graduates from undertaking any type of obstetric work in their first year of practice. Indeed, many of them will join the radical school in spite of the fact that they have not had obstetric training. If we are to beat this trend, we must develop more well staffed maternity and

Fig 1 Trend of maternal mortality in the United States and certain foreign countries. Deaths assigned to pregnancy and childbirth per 100 000 live births

this year than will die in labor, and statistics of life insurance companies show that women live longer than men. It is proper, however, to discuss what the movement actually has accomplished and how we can alter it if present results are not satisfactory.

When we attempt to review what the movement has accomplished, we are confronted with the fact that it has not reduced maternal mortality. Had it done so, there could be no argument about its value, because no one questions the merit of its aims. Yet the maternal mortality rate of the nation and of nearly all of our most populous states, has remained fairly constant during the years radicalism in obstetrics has been developing so rapidly. There has been a slight reduction in the rate due to improved public health conditions (Figs 1, 2, 3, 4, 5). But the mortality rate due to septicemia has shown no reduction. Moreover in some centers the maternal death rate actually has risen because the deaths which are termed 'preventable' are increasing faster than the 'non preventable' deaths are decreasing.

Nor does it appear likely that the maternal mortality rate will be reduced in the near future if the results of radical obstetrics continue as they have in the recent past. Last year I cited to the Clinical Congress of the American College of Surgeons essential facts of cesarean section as reported in the largest series of cases in our literature since 1930. The incidence was 7.5 per cent in 524,117 births (12,055 cases) with a surgical mortality of 4.1 per cent. This high mortality assumed added importance because cesarean section was responsible for one fourth of all the maternal deaths after the seventh month of pregnancy in the areas covered by this report.

The well trained radicals insist that it is unfair to judge the movement by maternal mortality figures because most deaths occurred in the practice

Fig 2 Trend of maternal mortality in New York

of untrained men. Nor do they feel responsible because such men join the movement and under take obstetric operations that they have not been trained to do. That almost every known type of specialist in medicine undertakes major obstetrics is shown in all recent mortality reports. In final analysis however, it is evident that he who is not interested in radicalism or conservatism in obstetrics must look directly at results. The facts are that the maternal mortality rates in this country have been too high, suffer in comparison with those of other countries, and have not been properly reduced. The improvements in operative technique and preparation and after care of the patient which have lowered operative mortality rates in surgery have failed thus far to do the same in obstetrics. Maternal mortality rates may not interest the untrained obstetrician but they vitally interest the Federal Government. In these days when the normal increase in population is being retarded by voluntary birth control a national mortality rate unduly high demands the very serious consideration of a medical profession that is not anxious to participate in state medicine.

It is evident that the new school of obstetrics needs proper molding by the control of the men and the procedures which are causing a high maternal and fetal mortality. At first sight the task seems Herculean because radicalism has developed in the face of active opposition of nearly every leading teacher of obstetrics. Yet the movement can be combatted by creating the sentiment in the profession that only well qualified obstetricians should be allowed to undertake major obstetric surgery. Conditions in obstetrics are no worse than they were in surgery 25 years ago when the American College of Surgeons began its task of educating the American surgeon. Education rather than legislation will solve the problem. Fortunately, the profession is becoming more and more interested in higher medical education.

Many agencies are doing what they can to improve the obstetric education of the physician, working chiefly through some type of brief post

solution is taken, the excess fluid is eliminated very slowly within 24 to 48 hours. If water is taken before the consumption of food, it will be eliminated rapidly. However, if taken after the consumption of food, it will be retained and stored with the food until the food becomes oxidized.

Positive water balance The intake of water may exceed the output, in which case a positive water balance will be established. This may be due to an excessive consumption of fluid, or to an interference with the output. Pathological changes which interfere with normal kidney function may result in a positive water balance. This fluid may accumulate in the intracellular spaces, producing a visible edema, or it may become bound in the cell protoplasm, in which case little or no evidence of edema is apparent. Muscles can store a considerable amount of intercellular water. Normally half the body water is held within the muscles. The retention of fluids can be most easily elicited by a visible or palpable edema or by an abnormally rapid gain in weight.

Pregnancy normally is characterized by a positive water balance. This retention of water is most marked in the last half of the gestation. The generalized tendency to edema in pregnant women may be the cause or the effect of this positive water balance.

The fetus may be regarded as a fast growing tissue of the mother's body consuming considerable water. The placenta likewise enlarges rapidly leading to marked retention of fluid. The turnover of water may be correspondingly large, so that the total water requirement of the mother may become disproportionate to the surface area.

This permanent increased fluid supply, cellular and intracellular in character, is evidenced by the ease with which edema develops late in pregnancy. The blood volume gradually increases so that at term the total volume averages 23 per cent greater than in the non-pregnant individual. This blood volume increase is a blood dilution, for the increase in the hemoglobin and the cellular constituents does not keep pace with the increase in the blood plasma. This altered fluid metabolism of normal pregnancy necessary for both the growing fetus and the preparation for labor can be easily upset and result in pathological complications of serious import. An increased positive water balance is thus a characteristic finding in most of the late toxemias of pregnancy. A decreased blood volume with a concentration of the cellular constituents is associated with severe pre-eclampsia and eclampsia.

In this discussion the endocrine influence on water balance has not been considered. Numerous

experiments indicate that the posterior lobe of the pituitary gland exercises an important function in water metabolism. There is no doubt that this function becomes of even greater importance in pregnancy. The physiological hypertrophy of the pituitary gland may be the cause of this increased function. Dieckmann and Michel have demonstrated that the parenteral injection of extracts of the posterior lobe of the pituitary gland in patients with pre-eclampsia or eclampsia will produce a decrease in volume of urine, an increase in the chloride concentration, and a rise of blood pressure. These significant findings indicate the rôle of this gland in normal pregnancy and particularly in the toxemias of pregnancy.

The effect of the adrenal glands on water metabolism in pregnancy is likewise little understood. We know, however, that these glands influence the metabolism of sodium chloride and therefore play an important rôle in water balance. Just how these facts concern themselves with pregnancy toxemias is not known, but certainly chloride balance and water balance are intimately associated.

Negative water balance Negative water balance results when the available supply of water to the body diminishes below normal levels, either as a result of decreased intake or because of an interference with gastro-intestinal absorption. Thus, starvation, vomiting, and diarrhea result in an interference with the fluid intake. There may be an excessive loss of water so that the normal balance cannot be maintained. This may be due to hemorrhage, loss of fluid from serosal surfaces, or damaged skin (burns, blisters). It may result from excessive loss due to sweat, saliva, fistulas, etc. There may be increased output by way of the kidneys such as in diabetes mellitus or insipidus.

Dehydration is first manifested by an increased thirst. It is characterized by a shrinkage of the subcutaneous tissues, a dry, hard, leathery skin, a decreasing urinary output, rapid loss of weight, anhydration fever, and a retention of acid radicals resulting in an acidosis. In severe cases of dehydration there is a decrease in the blood volume, with a resultant increase in hemoglobin, cell volume, serum protein, and non-protein nitrogen.

Hyperemesis gravidarum is chiefly characterized by a negative water balance. In this condition the water consumption may be normal but the available supply to the body tissues is decreased because of the continued vomiting. All the symptoms and findings of dehydration appear, depending upon the severity of the condition. The successful treatment depends, to a large extent, on the re-establishment of a normal water balance.

obstetric wards in well managed general hospitals so that more men yearly can receive adequate practical training. Moreover, the American College of Surgeons by constant effort finally must make it as difficult for the untrained man to do

major obstetrics in approved hospitals as it has made it for an untrained surgeon to do major surgery. The profession should not permit its members to learn practical obstetrics entirely from private patients.

WATER BALANCE IN RELATION TO TOXEMIAS OF PREGNANCY

M. EDWARD DAVIS, M.D., F.A.C.S., Chicago, Illinois

WATER is the chief constituent of all body tissues. It accounts for approximately 65 per cent of the total body weight. It is necessary to all physiological functions. As a vehicle or as a solvent it conveys to the body cells all the materials necessary for life and carries off the waste products of normal metabolism. Water is present in the body in two forms. It may be intimately bound in the cell protoplasm, bound water, or it may be present in the intracellular spaces, free water. When demands are made upon the supply of water in the body the intercellular fluid is readily available and is consumed first, after which the cells give up their bound water. Cellular fluid is contained largely within the muscle cells. An excess is not easily discernible so the body can add an appreciable amount to this store without noticeable evidence of the increase. However, when extracellular water increases considerably in amount it manifests itself readily as edema.

Water balance. Normally the body maintains a balance of water by regulating the output to the intake. Thus the output increases with an increased intake and diminishes when the intake decreases. Adolph has estimated that the average sized man uses approximately 3,400 cubic centimeters of water per square meter in 4 hours. This water is supplied to the body by the liquids consumed and by the various foods which vary in their water content. The metabolism of an average mixed meal of 3,000 calories furnishes 300 grams of water, but as the meal is consumed at the table it contains approximately 2,000 cubic centimeters of water.

The output of water occurs largely by way of

the kidneys but a considerable amount is lost by the lungs (300 cubic centimeters), by the skin in the sensible way or sweat (200 to 400 cubic centimeters) and in the insensible way (1 cm^2) and by way of the alimentary canal (100 cubic centimeters). These latter routes lose varying amounts depending on temperature, humidity and muscular activity.

The circulation serves as a distribution system for the body fluids. Ingested water is rapidly made available to all the body cells and the excess disposed of through the outgoing channels. Despite this rapid interchange of fluids the blood volume remains remarkably constant for an individual.

A rapid and serious drop in blood volume such as takes place in hemorrhage is quickly compensated by an increase in plasma volume through the passage of fluids and serum protein from the tissue spaces into the circulation. The increase in plasma volume persists until new hemoglobin is produced. Marked reductions in blood volume are associated with a marked increase in the plasma constituents hemoglobin, cell volume and plasma proteins. This hemoconcentration is present in serious disorders associated with an abnormal water balance. Pre-eclampsia and eclampsia may exhibit blood concentration and a reduction in blood volume.

When water is consumed a slight blood dilution occurs. The excess fluid is stored in the tissues and perhaps in newly opened capillaries. With an increased urinary excretion this accumulated fluid is gradually eliminated. The water that is drunk is usually excreted in the urine within 2 or 3 hours. The insensible loss of water increases in amount so the body usually ends up with somewhat less water than before the ingestion of the fluid. The same result is obtained by drinking an isomolar salt solution. On the other hand if sodium chloride

Presented at the Symposium on Obstetrics and Gynecology before the Clinical Congress of the American College of Surgeons, Chicago, October 25-29, 1937.

cells, so that the output of chlorides in the urine diminishes. These trends are aided by a gradual loss of plasma volume from the circulation containing electrolytes and serum protein.

Following delivery this blood concentration rapidly disappears. As the blood dilutes, water, electrolytes, and serum protein pass from the tissues into the blood stream. Once this reversal takes place, it is rapidly accelerated until the normal balance between circulation and tissues again is restored. The failure of this dilution to take place in the toxemias of pregnancy is a finding of great import, for it usually heralds a grave prognosis. One can, therefore, follow the course of the blood concentration as an important prognostic aid in the treatment of pre-eclampsia and eclampsia.

TREATMENT OF PRE-ECLAMPSIA AND ECLAMPSIA

In the treatment of these toxemias, the normal restoration of water balance is of prime importance. Theoretically, this can usually be accomplished by diminishing the intake of fluids and increasing the output. Arnold and Fay have developed a therapeutic regimen which consists of a limitation of fluid intake below the fluid output and an increase of the output by a rapid dehydration of the patient through purgation, spinal fluid drainage, the intravenous use of hypertonic glucose solutions, and the intravenous use of magnesium sulphate. These authors thus make use of all the avenues of fluid loss by the body, except bleeding. They report excellent results.

The treatment of these toxemias at the Chicago Lying-in Hospital likewise emphasizes the importance of establishing a normal water balance. To accomplish this, however, the intake of fluids is rarely restricted beyond normal requirements. The loss of excessive body fluids is encouraged by cutting down the salt intake to negligible amounts, thereby favoring a shift of fluid balance from the tissues to the blood stream. The change in sodium balance is followed by a change in water balance so that an increased fluid elimination takes place. When diet and the elimination of salt intake fail to accomplish an increased loss of body fluids and sodium chloride, hypertonic glucose solutions are used to establish an adequate diuresis, thus increasing the output of fluids by the kidneys. Once a reversal of water balance is initiated, the process continues with increasing speed.

When hypertonic glucose solution is introduced into the circulation, the resultant increased osmotic pressure draws fluids into the circulation. The glucose passing into the tissues replaces the sodium chloride in the cells and this chloride finds

its way into the circulation. Chemical studies indicate that glucose actually replaces serum chloride. The loss of chlorides from the tissues into the circulation likewise results in the loss of tissue fluid. The increasing blood volume produced by this mechanism results in an increased urinary output, together with a marked increase of chlorides in that urinary output. The use of hypertonic glucose solutions, therefore, aids in breaking up the vicious circle which has resulted from the increasing positive water balance. The continued intravenous use of hypertonic glucose solution tends ultimately to restore a normal water balance. Practically, the successful dilution of the blood by this means is a reliable index of the success of the therapy. Failure to produce dilution of the blood by increasingly more concentrated solutions indicates the severity of the toxemia.

If an individual is given 500 cubic centimeters of a 20 per cent glucose solution intravenously within a period of 30 minutes, a prompt and satisfactory diuresis occurs. A more marked reaction takes place when 30 per cent hypertonic solutions are used and even a better response when 50 per cent solutions are used. However, when more than 200 grams of glucose are given rapidly, there is a very marked glycosuria. It has been found that the more sugar that is spilled in the urine, the less toxic material is excreted. In the treatment of the toxemias of pregnancy, therefore, it seems logical to use 20 per cent solutions unless the volume of fluid injected into the circulation is dangerous to the patient because of a damaged cardiovascular system.

Where hypertonic glucose solutions have failed to cause a blood dilution and produce a satisfactory diuresis, acacia has been suggested and used. This substance occasionally succeeds in producing a diuresis when glucose solutions have failed. However, its use is not without danger as severe reactions have been reported.

It has been demonstrated that the intravenous administration of hypertonic glucose solutions dilates the capillaries in the fingernail bed. Thus, it may serve to exert a favorable influence in the toxemias of pregnancy, particularly the convulsive type, in which vessel spasm may be an important factor in the causation of the convulsions. The dilatation of the capillaries in the kidney results in an increased blood supply with its concomitant increased urinary excretion.

TREATMENT OF NON-CONVULSIVE TOXEMIA

Prophylactic. The careful observation of the woman during pregnancy at frequent intervals offers the best safeguard against the development

The toxemias of pregnancy are a heterogeneous group of complications incidental to pregnancy. Hyperemesis gravidarum, which is usually grouped with the toxemias has nothing in common with the late toxemias. However, in a discussion of water balance it is well to include this condition for the present treatment of this complication concerns itself largely with the restoration of normal fluid balance.

The classification of the late toxemias of pregnancy has been the subject of much discussion in recent years. There has been a general tendency toward the simplification of this classification. At the present time the toxemias can be grouped under the following headings: pre-eclampsia and eclampsia, essential hypertension, vascular renal disease, nephritis and nephrosis. Although there is a disturbed water balance in all of these toxemias, nevertheless we are concerned chiefly with pre-eclampsia and eclampsia. It is here that the most marked variations in fluid metabolism occur. It is here too that the proper approach to the treatment offers the best results.

We are just finishing an epoch in the treatment of the late toxemias of pregnancy wherein the surgical termination of gestation was the most important principle in the treatment. It was felt that the termination of pregnancy offered the one certain means of influencing the course of the disease since the exact etiology of these conditions is unknown. The end of the gestation will usually influence favorably the course of a toxemia, but the surgical manipulations necessary for this termination may prove extremely detrimental to the best interests of the patient. Cesarean section is probably the most dangerous method of treating eclampsia for it carries with it an extremely high maternal mortality. A large number of statistics have accumulated to show that operative intervention in eclampsia, particularly cesarean section, offers the worst prognosis for the patient in a serious condition. Furthermore in the treatment of pre-eclampsia, operative intervention likewise is a more dangerous procedure than treatment by medical means which is followed if necessary, by the induction of labor by simple procedures. The high maternal mortality in the toxemias of pregnancy as well as in cesarean section is probably due to the high incidence of operative interference. It thus becomes necessary to understand the underlying basic principles in the medical treatment of these conditions in order to decrease the high incidence of operative interference.

The late toxemias of pregnancy—pre-eclampsia, and eclampsia—are characterized by a marked disturbance of water balance. The normal pos-

sitive water balance of pregnancy probably contributes to the ease with which a pathological water balance develops. Clinically the earliest manifestation of pre-eclampsia may be the sudden gain in weight. Whenever a patient gains 3 or 4 kilograms in a week or 10 days one must assume that this increased weight represents to a large extent an increased water storage. Edema may or may not be present, depending upon whether this fluid is largely intercellular or extracellular.

With the retention of water there occurs a retention and storage of chlorides for tissues can not store water in the absence of sufficient chlorides. The blood chlorides however fail to increase in amount even during the convulsive state, for a balance is always maintained between the blood chlorides and the tissue chlorides. This increased chloride content of the body tissues represents, therefore, an increased intake and retention of chlorides rather than a decrease in the chloride output.

If one now carefully estimates the intake and the output of fluids, the increasing positive water balance is readily detected. The urinary output which accounts for a considerable amount of the fluid lost, gradually diminishes. The urine chlorides likewise diminish in amount. In the pre-eclamptic stage just prior to the convulsive seizure the output of urine may decrease tremendously and with the onset of the convulsions an actual anuria may set in. This sudden elimination of the most important avenue of fluid output must be ushered in as a result of vessel spasm in the extensive capillary beds. This vascular constriction may be the final contributing factor in the production of the convulsive stage.

Dieckmann and his associates have demonstrated that pre-eclampsia and eclampsia are likewise characterized by changes in the blood volume. When the clinical symptoms of hypertension, albuminuria and edema become marked a decrease in the blood volume begins to take place. This decreased blood volume is best noted by the concentration of the blood constituents, thus the serum protein, hemoglobin and cell volume increase in amount by the passage of water containing electrolytes, glucose and non-protein nitrogen into the patient's tissues. A very small diminution of blood volume is present in normal pregnancy at the onset of labor but in the toxemias of pregnancy this reduction is very marked. This hemoconcentration adds to the disturbed water balance which already exists. The intracellular and extracellular water is greatly increased in amount. There is a marked increase in the storage of chlorides in the tissue spaces and

should always favor termination. When the baby is at the borderline of viability, there is a tendency to continue medical treatment as long as possible.

In general, the induction of labor should be as simple as possible. Medical induction supplemented by the simple rupture of the membranes usually suffices at or near term. In some cases the insertion of a small hydrostatic bag into the cervix is necessary to start labor. Cesarean section should be considered but rarely and usually only in the event that there is another indication in addition to the toxemia. It should always be done under local anesthesia.

TREATMENT OF CONVULSIVE TOXEMIA

General. The constant observation of the patient with frequent determinations of the temperature, pulse, respiration, and blood pressure is extremely important. External stimuli should be eliminated as much as possible for they tend to start the convulsions.

Sedation. The convulsions can be controlled by a number of sedatives. Morphine sulphate is probably the most effective drug. It can be given in doses of $\frac{1}{4}$ grain every hour until the convulsions cease or the respirations decrease to 12 per minute. Luminal-sodium, 5 grains every 8 to 12 hours, can be given subcutaneously. If magnesium sulphate is used its administration should be limited to intramuscular injection. Ten cubic centimeters of a 25 per cent solution can be given after each convulsion.

Water balance. A careful check on the urinary output is absolutely necessary in the conduct of eclampsia. A retention catheter should be placed in the bladder so that all the urine can be collected. The intravenous injections of 500 to 1000 cubic centimeters of a 20 per cent solution of glucose administered in 40 to 60 minutes can be given 2 or 3 times daily to promote a diuresis. If a satisfactory response is not obtained from this concentration, a 30 per cent glucose solution can be used. Sufficient glucose should be administered to insure a urinary volume of at least 30 cubic centimeters per hour.

Termination of the gestation. When the convulsions have been brought under control and a satisfactory urinary output has been established by the intravenous administration of hypertonic

glucose solutions, the interruption of pregnancy can be considered. The rupture of membranes usually suffices to initiate labor. Where the cervix is long and uneffaced, the insertion of a small bag into the uterus aids in the induction of labor. Cesarean section is *almost never indicated*. This operation should be performed only in the event that a cephalopelvic disproportion exists.

Diet. Nothing is given by mouth until the patient is conscious. The patient can then be fed through a nasal tube, starting with 50 cubic centimeters of a 10 per cent solution of karo syrup and increasing by 50 cubic centimeters per hour until a total of 200 cubic centimeters per hour is reached. The total intake and output of fluids should be carefully checked until the clinical findings improve.

of serious toxemia. At the Chicago Lying in Hospital the incidence of toxemia is about 7 per cent but only rarely does a case of convulsive toxemia develop among the patients under observation. Adequate prenatal care should include a close check on the patient's weight gain, in addition to blood pressure determinations and urine analysis. Clinically, the earliest manifestation of a developing toxemia may be an unusually rapid weight gain which is indicative of a disturbed water balance with its fluid and sodium chloride retention. Edema may or may not be present at this time. The average weight gain of a group of normal women during pregnancy was 21 pounds contrasted with a gain of 44 pounds for women who developed toxemias of pregnancy. The weight gain is distributed in such a way that the patient has no increase in her weight at the end of the first trimester that she gains a half pound per week during the second trimester and a pound per week during the last 3 months. Whenever a patient has a weight increase of 6 or 8 pounds in a period of a week or 2, one must assume this sudden increment represents largely increased water storage. Prompt treatment tending to restoration of a more normal water balance should be instituted.

Mild cases—ambulatory treatment—rest. The patient should be encouraged to secure at least 10 hours of sleep nightly. In addition she should rest for an hour or two morning and afternoon. She may be nervous, irritable, and unable to secure proper rest in which case phenobarbital $\frac{1}{2}$ to $1\frac{1}{2}$ grains 2 or 3 times daily may serve as a sedative. It may be necessary to rearrange her household responsibilities before she can secure the desired rest.

Diet. This should consist largely of carbohydrates and a limited amount of proteins. It should be *salt poor*. If the excessive weight gain is not due entirely to water retention, fats should be omitted from the diet. A maintenance diet of a quart of milk, eggs, some meat, unlimited fruits and vegetables can be used for a prolonged period without detriment to the patient.

Water balance. The trend of the fluid balance can be ascertained by carefully noting the weight and by measuring the intake and output of fluids. A loss in weight which continues over several days or longer denotes a loss of tissue fluid and a tendency toward the restoration of a more normal water balance. This is likewise indicated by a urinary output which exceeds the fluid intake. The edema should disappear. The return of a more normal water balance should be reflected in a decrease of the blood pressure and a diminution in the albuminuria.

Severe cases—hospital treatment—rest. If the patient fails to improve under management in the home, hospitalization is usually indicated when this is possible. The patient should now have complete bed rest, preferably in a quiet environment. Phenobarbital $1\frac{1}{2}$ grains 3 times daily or luminal sodium 5 grains subcutaneously, once or twice daily, can be used as a sedative.

Diet. The diet should be as *salt poor* as possible. It should consist of fruits, vegetables, eggs, cereal, toast, tea or coffee. If the toxemia is very severe in character, the diet should be restricted largely to fruits, vegetables and fruit juices but this limited diet should not be maintained longer than a week or 10 days.

Water balance. The water balance should be determined by measuring the intake and output of all fluids. The output of fluids should exceed the intake until all evidence of edema and the excessive weight gain have disappeared, after which they should balance.

The restoration of a more normal balance is aided by increasing the fluid output through the use of hypertonic glucose solutions. The rapid (30 to 40 minutes) intravenous injection of 500 cubic centimeters of 20 per cent glucose solution 2 or 3 times daily usually provokes a diuresis and increases the fluid output. It may be necessary to use a 30 per cent solution to obtain a satisfactory urinary response. If there is evidence of cardiac decompensation the fluid intake should be limited and 100 to 200 cubic centimeters of a 50 per cent solution should be used. The intravenous fluids can be continued as long as necessary to maintain a satisfactory urinary output.

Termination of the gestation. The termination of the pregnancy offers the one certain way of altering the course of the toxemia. Delivery usually results in blood dilution, increased urinary output, rapid loss of chlorides and a change toward a normal water balance with subsequent improvement in the patient's clinical condition. It is important therefore to initiate labor before the onset of the convulsive phase and before irreparable damage to the patient ensues.

The pregnancy should be terminated (a) if the patient's symptoms and findings fail to improve under treatment, (b) if cerebral, visual or gastrointestinal symptoms develop, (c) if jaundice develops, (d) in the presence of cardiovascular impairment, (e) if a favorable water balance cannot be produced because of a persistent oliguria or anuria or because of an increasing blood concentration. In the presence of a viable baby at or near term the question of terminating the gestation is not difficult to decide, and the decision

manipulation of the nerves of Frankenhaeser's plexus which causes the patient to groan, even under deep anesthesia, at the time of clamping the cervical supports during a vaginal hysterectomy.

Essential dysmenorrhea has become a topic of greater interest since recognition that it may be a cramping of the uterine musculature ascribable to an excess of the estrogenic factor, opposed by the corpus luteum hormone. Endocrine therapy has not yet been proved to be of distinct value in relief of this affection, but the future is promising.

I have been slow to accept resection of the superior hypogastric plexus (the presacral nerve) as the procedure of choice in cases of intractable essential dysmenorrhea. We have resorted to nerve resection over a period of many years, but chiefly in selected cases in which other pathology required surgical intervention. Gradually the number of cases has grown and some operations have been performed for the sole purpose of presacral nerve resection. My records indicate that not a single patient has failed to obtain relief. Nevertheless, I still look upon this operation as an important undertaking, to be resorted to only in intractable cases after other measures prove futile.

Nerve blocking by means of alcohol injection in the region of Frankenhaeser's plexus was advocated by Bloss in 1929 for the relief of dysmenorrhea and other deep-seated pelvic pain. The procedure as employed by the vaginal route has not become widely popular and some instances of necrosis and inflammatory reaction have been recorded.

Acquired dysmenorrhea. Particular emphasis should be accorded the part played by uterine obstructions in the causation of pelvic pain, but the subject of obstruction is an important topic which we may well pause to consider. Obstructed drainage from the uterus is quite as serious as is inadequate drainage from other regions of the body, and in these days of radium therapy and cauterizations and amputations of the cervix, interference with the free flow of menstrual blood and uterine secretions is encountered almost daily in the practice of a busy gynecologist. The pain of obstructed uterine drainage varies from ill-defined pelvic discomfort to severe cramps, accompanied by inadequate or prolonged menstruation, a dark or tarry flow is characteristic but not pathognomonic, for a dark flow also occurs with disturbed ovarian function. Employment of a fine Hegar dilator verifies the diagnosis, although the evidence may be inconclusive without confirmation under anesthesia.

If my individual experience is a criterion, it will eventually be regarded as a surgical error to use radium, or make repeated endocervical topical applications, or apply the cautery within the cervical canal, or amputate the cervix of the uterus, or even administer expectant care to a patient with notable endocervical disease, without prolonged and attentive observation thereafter directed to the maintenance of patency of the cervical canal.

"Reversed menstrual drainage" is a term which might advantageously be coined to express the pathogenesis of a group of affections which develop insidiously and persistently, with disturbance of pelvic function in the early stages, and eventual development of extensive pelvic pathology. Although many are contrary minded, accumulated evidence furnishes ever-increasing support to Sampson's theory that retrograde menstruation and implantation of spilled fragments of Muellerian tissue account for the majority of cases of pelvic endometriosis. The cause of reversed drainage is found most frequently in persistent retrodisplacement of the uterus, but laxity of uterine supports with relaxation sufficient to permit temporary retrodisplacement accounts for many cases. Less well recognized, and extremely important, is a large group of cases in which obstructed drainage from the uterus produces a backflow and a pelvic spill. If the opened abdomen reveals endometriosis in the absence of retrodisplacement or relaxed uterine supports, one may unhesitatingly diagnose and can demonstrate an obstructing lesion of the uterus. There is only one exception—a history of intrauterine instrumentation which might have produced a spill. The obstruction need not be a stricture, a projecting submucous fibroid or an occluding polyp may be equally effective.

I shall not stop to dwell on the importance of menstrual backpressure in the causation of adenomyosis and fibroids of the uterus, but even my own limited personal experience suffices to impress me with the importance of this factor in the etiology of uterine tumors. Still further, I am in sympathy with the sentiment expressed by Graves, that the greatest avoidable cancer menace is inadequate genital drainage. And I would add that we must not overlook microscopic obstruction, for it rivals gross obstruction in importance.

Pelvic toothache. In search for a widely descriptive term I have coined this expression to cover the essential symptom in a considerable group of patients who travel from doctor to doctor without relief. I say this in all humility, for recognition of the underlying nature of the complaint often

ABDOMINAL AND PELVIC PAIN—FROM A GYNECOLOGICAL VIEWPOINT

ARTHUR H. CURTIS, M.D., F.A.C.S., Chicago, Illinois

IT is not my intention to present a comprehensive gynecological survey of abdominal and pelvic pain, but rather to concern myself with selected topics which appear to merit our attention. If I deviate from the subject of this paper and I shall do so, it will be with malice aforethought, and with the object of adding to the interest of my offering in this I beg your indulgence.

Pain in the right upper quadrant. In 1929 I called attention to the incidence and clinical significance of anterior liver surface adhesions. I refer to adhesions in the subdiaphragmatic anterior liver surface region in the absence of generalized adhesions or other local pathology which might account for their presence.

All told, since a detailed record was begun in 1928, I have operated on 56 patients with adhesions ascribable to gonococcal infection. Eight other atypical cases were probably ascribable to the gonococcus. Strangely enough only 10 cases throughout these 9 years were either apparently or definitely non-gonorrheal. These do not include non-operated upon patients, of whom there have been a score or more some with evidence of gonococcal infection in the active stage many more with a history of genital disease and associated characteristic symptoms in the right upper quadrant 'liver region pain'.

The route traveled by the gonococcus in reaching the subdiaphragmatic space has not been determined. It is assumed that it is by a process of direct extension—presumably along the para-vertebral gutter.

There may be no history of pain; the discovery of the adhesions being merely a casual finding incidental to an abdominal operation for tubal disease. More frequently, postoperative inquiry yields a story of a former right-sided pleurisy or gall bladder trouble or perhaps right intercostal neuralgia.

Although most commonly recognized incidental to abdominal exploration, symptoms of peritoneal involvement in the region of the liver are not

uncommon during the acute stage of gonorrheal disease of the pelvic viscera. The symptoms are seldom noted by the attending physician because they are obscured by the more severe pelvic symptoms or they escape recognition because the upper abdominal distress is ascribed to gaseous distention, a common complaint in these patients. Once looked for, the diagnosis during the acute stage is simple; there is localized distress in the right upper quadrant in the region of the liver often accompanied by a friction rub.

From the viewpoint of operative intervention nothing is necessary, nor is relief of the pain a serious matter, for it seldom exceeds that of a moderate pleurisy and as a rule is limited to a period of a few days. But from a diagnostic viewpoint, this is an important affection. In the acute stage it may be confused with biliary colic, or acute pleurisy. It is especially in relation to pelvic disease, however, that the recognition of anterior liver surface adhesions is important. On a few occasions I have been able to speak with greater certainty about the diagnosis of a pelvic mass because questioning has yielded a history of liver adhesion pain. At operation before exposure of the pelvic viscera initial palpation of these adhesions in the upper abdomen is pathognomonic evidence of tubal disease particularly in differentiation of the etiology of hydrosalpinx, of salpingitis isthmica nodosa and of pelvic adhesions of undetermined etiology (the accompanying presence of anterior liver surface adhesions bespeaks a gonococcal infection).

Dysmenorrhea. For the sake of clarity I shall now describe the pelvic plexus more commonly known as the uterovaginal plexus, the cervical ganglion, or the ganglion of Frankenhauser, which furnishes the chief nerve supply to the pelvic organs. It is because there is much erroneous description and much confusion concerning this plexus that a brief description appears appropriate. It is a bilateral thin sheet of nerve fibers and fascia spread out over an area of by 3 centimeters upon the lateral aspect of the ampulla of the rectum situated in the broad ligament at the level of the cervix; the plexus is somewhat lateral to the lateral fornix of the vagina upon the posterior surface of Mackenrodt's ligament. It is

There is only one exception—a history of intrauterine instrumentation which might have produced a spill. The obstruction need not be a stricture, a projecting submucous fibroid or an occluding polyp may be equally effective.

I shall not stop to dwell on the importance of menstrual backpressure in the causation of adenomyosis and fibroids of the uterus, but even my own limited personal experience suffices to impress me with the importance of this factor in the etiology of uterine tumors. Still further, I am in sympathy with the sentiment expressed by Graves, that the greatest *avoidable* cancer menace is inadequate genital drainage. And I would add that we must not overlook microscopic obstruction, for it rivals gross obstruction in importance.

Pelvic toothache. In search for a widely descriptive term I have coined this expression to cover the essential symptom in a considerable group of patients who travel from doctor to doctor without relief. I say this in all humility, for recognition of the underlying nature of the complaint often

completely escaped my detection until recent years, and in many instances the etiology and exact diagnosis of the nerve pain still remain elusive. Sometimes a vague vaginal pain is unmistakably localized in an apparently innocent rectocele, but it is to deep-seated pain that we can now most profitably direct our attention.

Pain ascribable to lesions of the pelvic viscera is apparently always transmitted through the pelvic plexus (Frankenhauser's ganglion). A majority of the afferent nerve fibers travel upward through the superior hypogastric plexus the so-called presacral nerve. Resection of the presacral nerve may, apparently, be depended upon to relieve dysmenorrhea, but pain ascribable to deep-seated cellulitis and lesions in other more remote regions may demand other procedures.

James Young, of London, uses the term "broad ligament neuritis" to express the symptom complex produced by chronic cervicitis and believes that not only localized broad ligament pain but also distress more diffusely spread over the abdomen and back and extended down the thighs may likewise be explained on the basis of infection of the cervix. I am in accord with the thought that infection of the cervix particularly that associated with blocked drainage is an important factor in deep-seated pelvic pain, but we find that more widespread distress such as chronic aches in the lateral abdomen and groin and thighs is more often identified with arthritis and nerve root lesions.

Some years ago I became aware that an exhaustive and detailed history combined with a painstaking examination permits one to determine almost invariably whether a headache is of gynecological origin or requires the services of an orthopedist. In the course of those clinical studies many previously unrecognized tender spots were encountered. It was learned that poorly described and ill defined regions of distress can be accurately localized upon deep pelvic palpation with the patient placed in various positions with digital exploration directed along the entire pelvic wall, the sacrum and the coccyx. In this connection I wish chiefly to emphasize that there is definitely localizable pelvic pain outside the region of the pelvic viscera characterized by excruciating tenderness along the lumbosacral nerve roots, and that this pain along the wall of the pelvis although sometimes identified with cervicitis is characteristic of lesions of the bones, ligaments and fascia of the pelvis usually amenable to relief by the orthopedist and sometimes, when he fails, by the neurologic surgeon. X-ray study of such cases is commonly confirmatory of the pelvic findings, but the

gynecologist may be able to localize lesions which otherwise would escape orthopedic detection and he may demonstrate foci of trouble in an incipient stage before there are notable bony changes demonstrable by the x-ray.

In summarizing these remarks on pelvic tooth ache it may suffice to state that the gynecologist can often relieve pelvic suffering by preacral nerve resection or by treatment or removal of diseased genitalia but there are many other deep-seated neurological affections of the pelvis which we may detect because of our experience in pelvic examination which belong in the domain of the neurologic surgeon or in the hands of the orthopedist.

Postoperative distress. Postoperative adhesions are a cause of much suffering and I am an advocate of operative intervention for their relief. Local distress persistent after correction of intestinal disorders and stagnant elimination is almost pathognomonic of adhesions and does not commonly require x-ray study for confirmation of the diagnosis. The x-ray is helpful in selected cases but it is too gross to be depended upon in a great percentage of cases, just as it may be ineffectual in a search for the cause of a headache.

"Once adhesions, always adhesions" is an axiom which should not apply in present-day surgery of the lower abdomen. Adhesions above the level of the navel tend to recur despite careful technique. But lower abdominal and pelvic adhesions are amenable to correction if we are willing to operate deliberately painstakingly and gently with employment of rubber protective and avoidance of roughing the peritoneal surfaces with gauze.

If the pelvic structures are left rigid at the close of a pelvic operation by the abdominal route there is considerable hazard of subsequent discomfort on physical exertion and during sexual contact. There is a still greater incidence of an undesirable rigidity as an aftermath of operations by the vaginal route. Adequate support is imperative as is universally recognized, but we have failed to copy nature in leaving the tissues pliable and mobile. Like the modern tailor who is forever insistent on tight, good-looking clothes, the gynecologist may unwittingly be the cause of suffering. To produce a vaginal vault free from tenderness and a vaginal canal which is pliable and comfortable—adequately repaired yet not too tight—is difficult. Particularly in patients subjected to vaginal hysterectomy with at the same time a correction of a cystocele and a rectocele it is difficult to leave an adequate comfortable canal. In the repair of extensive relaxations of the ante-

rior wall together with rectocele, anatomical restoration may tempt one to connect the anterior and posterior incisions in the vaginal vault. It is preferable not to do this, but rather to leave a soft bed in the region of the posterior vaginal fornix, where nature originally provided a soft cushion. In closure of the cystocele wound the mucosal sutures may well include the underlying fascia, thus maintaining a normal deep concavity, in contradistinction to a tensely sutured less concave anterior wall.

In rectocele repair approximation of the levator ani may be indicated. But it is well to remember that nature placed very little muscular tissue between the vagina and the rectum and a repair with nothing more than firm musculo-fascial support overlying the rectum suffices in cases in which approximation of the levator ani produces a too tense perineum or undue constriction of the vaginal canal.

Dyspareunia Persistently painful intercourse during the honeymoon, and sometimes protracted thereafter until childbearing, when not ascribable to an inflammatory process is most often caused by traumatism of the anterior vaginal wall. Hasty coital entrance into a tight canal may be accompanied by a "hang" at the urethral meatus, which becomes everted and sags and often excruciatingly tender. The lesion is self-evident when searched for, although it escapes detection on casual examination. Suggestions to the husband and wife relative to the details of contact without injury commonly suffice, except in unusual cases in which perineotomy is required.

We have long been vaguely aware of the incidence of dyspareunia from dryness and from shrinkage of the tissues after the menopause, but we have been dilatory in affording relief. Only recently has there been adequate recognition of the severity of so called senile vaginitis and appreciation of the etiological importance of estrin deficiency in the causation of this disturbance. Endocrine therapy may restore the normal glycogen content in the vaginal mucosa and thus result in the return of the normal flora, normal vaginal acidity, and natural moisture of the tissues. Vaginal suppositories of cocoa-butter or other innocuous substances are helpful adjuncts.

Perineal pain Distress during labor, intractable pruritus, and neuralgic pain in the perineum may require unusual measures, such as nerve blocking or resection of the perineal nerves. Nerve blocking has some advocates among our obstetricians. Open operations for nerve resection have heretofore been neglected by most gynecologists or have been referred to the neuro-

logic surgeon. With the thought that these topics may be of interest, I shall digress to point out the anatomical landmarks of importance in nerve blocking of the perineum and in nerve resection for the relief of pruritus and kindred ailments.

Alcock's canal, formed by the fascia covering the obturator internus muscle, contains the internal pudic artery and veins and the pudic nerve. With the patient lying on her back with the thighs flexed, in the usual position for a perineal operation, the extended forefinger of the seated surgeon pointing into the depths in the region of the tuber ischium is directed toward Alcock's canal, which lies on the medial surface of the bone within the margin of the tuberosity and at a slightly lower level. This is a favorable site for anesthetic blocking of the pudic nerve.

A more detailed knowledge of the branches of the pudic nerve is necessary if resection is required for relief of intolerable itching (*pruritus vulvae*). One or two inferior hemorrhoidal nerves are given off soon after the nerve leaves Alcock's canal. The main trunk of the pudic nerve courses forward, becomes superficial, and divides into the perineal nerve and the dorsal nerve to the clitoris. The perineal nerve has 2 branches, 1 superficial, 1 deep. The first branch of the deep perineal nerve goes to the anterior half of the external sphincter ani and should be spared. All other branches may be destroyed. Surgically, the perineal nerve may be isolated, bilaterally, by a perineal incision parallel with and 1 inch mesial to the rami of the ischium and pubis, extending posteriorly to the anterior level of the anus. Dissection will reveal the posterior border of the superficial transverse perineal muscle, around which the nerve and vessels turn upward to reach the perineum. It will be remembered that the superficial perineal muscle is a firm band extending from the tuber ischium to the central point of the perineum. Tracing the fibers toward the nerve trunk enables one to find anastomoses with the other nerves which contribute to the sensory supply of the perineum. These are the perineal cutaneous branches of the ilioinguinal, genitofemoral, posterior femoral cutaneous, and the sacral and the anococcygeal nerves.

Cancer pain Many years ago Dr Watkins and I came to a realization that morphine is unsatisfactory as an analgesic in cases of genital cancer. The explanation is simple. Cancer pain is continuous. Morphine relieves suffering for not more than a few hours at the most. As the patient becomes habituated to the drug, continuously increasing dosage is required. Even with pain of moderate severity, considerable distress is evi-

completely escaped my detection until recent years, and in many instances the etiology and exact diagnosis of the nerve pain still remain elusive. Sometimes a vague 'vaginal pain' is unmistakably localized in an apparently innocent rectocele but it is to deep-seated pain that we can now most profitably direct our attention.

Pain ascribable to lesions of the pelvic viscera is apparently always transmitted through the pelvic plexus (Frankenhauser's ganglion). A majority of the afferent nerve fibers travel upward through the superior hypogastric plexus the so-called presacral nerve. Resection of the presacral nerve may apparently, be depended upon to relieve dysmenorrhea, but pain ascribable to deep seated cellulitis and lesions in other more remote regions may demand other procedures.

James Young of London uses the term 'broad ligament neuritis' to express the symptom complex produced by chronic cervicitis and believes that not only localized broad ligament pain but also distress more diffusely spread over the abdomen and back and extended down the thighs may likewise be explained on the basis of infection of the cervix. I am in accord with the thought that infection of the cervix particularly that associated with blocked drainage is an important factor in deep seated pelvic pain but we find that more widespread distress such as chronic aches in the lateral abdomen and groin and thighs is more often identified with arthritis and nerve root lesions.

Some years ago I became aware that an exhaustive and detailed history combined with a painstaking examination permits one to determine almost invariably whether a backache is of gynecological origin or requires the services of an orthopedist. In the course of those clinical studies many previously unrecognized tender spots were encountered. It was learned that *poorly described and ill defined regions of distress can be accurately localized upon deep pelvic palpation with the patient placed in various positions with digital exploration directed along the entire pelvic wall, the sacrum, and the coccyx*. In this connection I wish chiefly to emphasize that there is definitely localizable pelvic pain outside the region of the pelvic viscera characterized by excruciating tenderness along the lumbosacral nerve roots and that this pain along the wall of the pelvis although sometimes identified with cervicitis is characteristic of lesions of the bones ligaments and fascia of the pelvis usually amenable to relief by the orthopedist and sometimes when he fails by the neurologic surgeon. X ray study of such cases is commonly confirmatory of the pelvic findings, but the

gynecologist may be able to localize lesions which otherwise would escape orthopedic detection and he may demonstrate foci of trouble in an incipient stage before there are notable bony changes demonstrable by the x ray.

In summarizing these remarks on pelvic tooth ache it may suffice to state that the gynecologist can often relieve pelvic suffering by presacral nerve resection or by treatment or removal of diseased genitalia but there are many other deep seated neurological affections of the pelvis which we may detect because of our experience in pelvic examination which belong in the domain of the neurologic surgeon or in the hands of the orthopedist.

Postoperative distress Postoperative adhesions are a cause of much suffering and I am an advocate of operative intervention for their relief. Local distress persistent after correction of intestinal disorders and stagnant elimination is almost pathognomonic of adhesions and does not commonly require x ray study for confirmation of the diagnosis. The x ray is helpful in selected cases but it is too gross to be depended upon in a great percentage of cases, just as it may be ineffectual in a search for the cause of a headache.

'Once adhesions always adhesions' is an axiom which should not apply in present day surgery of the lower abdomen. Adhesions above the level of the navel tend to recur despite careful technique. But lower abdominal and pelvic adhesions are amenable to correction if we are willing to operate deliberately painstakingly and gently with employment of rubber protective and avoidance of roughing the peritoneal surfaces with gauze.

If the pelvic structures are left rigid at the close of a pelvic operation by the abdominal route there is considerable hazard of subsequent discomfort on physical exertion and during sexual contact. There is a still greater incidence of undesirable rigidity as an aftermath of operations by the vaginal route. Adequate support is imperative as is universally recognized but we have failed to copy nature in leaving the tissues pliable and mobile. Like the modern tailor who is forever insistent on tight good looking clothes the gynecologist may unwittingly be the cause of suffering. To produce a vaginal vault free from tenderness and a vaginal canal which is pliable and comfortable—adequately repaired yet not too tight—is difficult. Particularly in patients subjected to vaginal hysterectomy with at the same time a correction of a cystocele and a rectocele it is difficult to leave an adequate comfortable canal. In the repair of extensive relaxations of the ante

CESAREAN SECTION

JOHN R. FRASER, M.D., C.M., F.A.C.S., and DOUGLAS SPARLING, M.D., Montreal, Quebec

ONE of the important questions still engaging attention in obstetrics is the determination of the part cesarean section should play in the treatment of obstetrical complications

In the Canadian government report on Maternal Mortality (1935) three statements appear which will bear remembrance

1. In spontaneous deliveries the estimated specific mortality rate was 2.3 per 1000 live births, while in non-spontaneous deliveries it was 8.2

2. In 18 per cent of the delivered cases (221) a cesarean was done

3. Of women dying of eclampsia who were delivered, about a third followed cesarean section

The American Committee on maternal welfare in a special report on toxemias of pregnancy estimates that eclampsia and allied forms of toxemia are responsible for 30 per cent, approximately, of 15,000 maternal deaths in the United States each year. It is well, the report states, "to understand at the beginning that the toxemias are non-surgical conditions requiring medical treatment in the majority of cases. Careful examination reveals that the death rate in some localities is 20 per cent following cesarean section or other operative measures for eclampsia."

Perhaps at no time in the history of obstetrics has there been a more influential body of opinion directed toward the understanding and possible regulation of the rising incidence of cesarean section with its attendant risks, than at the present time. One year ago at the annual meeting of this College, Frank Lynch, director of the department of obstetrics and gynecology, University of California, made a most impressive contribution to the further understanding of this problem in an address dedicated to "More Conservatism in Cesarean Section." Many important facts emerged from this study. He established the fact that more than half of the cesarean deaths had occurred in women who previously had given birth to children through the normal birth passages. Some idea of the widespread performance of the operation may be deduced from the statement that cesarean section preceded 11 per cent of all puerperal deaths in or after the seventh month of

pregnancy in the 15 states reporting for 1927-1928. In point of fact 0.76 per cent of all women delivered in the United States in 1934 were by cesarean section. In hospitals the incidence rose to 2.8 per cent of all hospital births.

Table II prepared by Greenhill shows the steady rise in the incidence of the operation in a large hospital. Lynch draws attention, however, to the fact that even with this operative increase there has not been a compensating decrease in mortality generally.

The general and increasing popularity of the operation has not, as might be expected, led to a more precise clarification of the indications for its performance; on the contrary, as the result of sporadic successes the list of relative indications has been widely extended with resultant confusion. The sound principles which have always governed the indications for operation are being lost sight of, in a desire to deliver the women through the abdomen when and if any serious obstetrical abnormality arises.

It is perfectly true that in carefully selected cases under proper conditions and before labor has commenced the operation may be carried out successfully with a mortality of 1 per cent or even less. Witness the series reported by Greenhill, Arnott of Lynch's clinic and Paul Bar of Paris. On the other hand when conditions are not ideal

dent after 2 or 3 hours and from then on one is in a quandary whether to repeat the medication or to prolong the suffering. The net result is a patient who is made to suffer much of the time because morphine has been rightfully withheld as long as possible, added to the ravages of the disease and to part time suffering ascribable to incomplete analgesia is superimposed addiction to morphine in itself a terrible affliction. With aspirin and codeine, and perhaps with kindred remedies which are not habit forming the average patient can be maintained in peace and in relative comfort until the end. One should not be too sparing with codeine, for Walter Haines repeatedly stated that $\frac{3}{4}$ grain of morphine is the equivalent of 2 grains of codeine, and the latter is habit forming in the rarest of instances. Our customary dosage in cancer cases is 1 grain, seldom more than $1\frac{1}{2}$ grains. Sometimes codeine produces nausea, but not often. Its chief assets in cancer are that it is not habit forming and habituation does not necessitate increasing dosage. Discussion of other drugs would lead us too far afield and would also carry me beyond my depth.

I cannot extricate myself from the subject of cancer without mention of other means of affording relief from intractable pain. It has been my fortunate experience that fully 90 per cent of patients require nothing more than aspirin, codeine, and attentive care. In the terminal weeks when the patient goes from bad to worse, I have no objection to morphine, provided life expectancy is short. My experience with intrathecal administration of alcohol is too limited to warrant an expression of personal opinion. By the grapevine route I gather that it is not uniformly

satisfactory but gives considerable, although in adequate, relief in most cases. With the patient in a lateral position for lumbar puncture, the most painful side of the body uppermost, the hips elevated on a pillow, and the head lowered a few cubic centimeters of spinal fluid are withdrawn and discarded before slow instillation of not more than 0.8 cubic centimeter of absolute alcohol. The patient is maintained in this position for 20 minutes or more, and the head kept lowered for an additional hour at least. Relief may come only after several days. If the pain is bilateral, spinal instillation with the other hip uppermost may be resorted to later. Repeated treatments should be given with circumspection, and rarely in an amount of more than 1.0 cubic centimeter.

Bladder disturbances and other complications are seldom serious but degenerative changes are a sufficient hazard to contra-indicate this therapy in other than those whose prognosis is hopeless.

Chordotomy is out of the gynecological operative picture, but proper care of our patients requires an acquaintance with its indications and limitations. Extracts from a letter of Max Yee, September 30, 1937, are of interest. He states:

We are still doing chordotomies for relief of intractable pain, not only of the pelvis but as high as the cervical region. I still prefer to perform the operation under local anesthesia, so that I can test the patient to determine whether I have a sufficiently high level of analgesia. A high chordotomy at the level of the first or second thoracic vertebra is less difficult than at a lower level and is easier on the patient.

TABLE III.—STATISTICS COMPILED BY BLACKER

	Number of cases	Maternal mortality	
		No	Per cent
Bar	97	0	
Schauta	128	0	
Kerr and Holland	1591	26	1.6
Armand Routh	469	14	2.9

rate of barely 2.2 per cent. In our disproportion group 187 of a total of 216 cases, i.e. 87 per cent were operated upon before labor ensued, with a mortality rate of 1.3 per cent. This mortality was a small proportion of that for the entire series, although it represented the end-result in the largest single group of the series, cases in which infection might reasonably have been expected inasmuch as the history of many of them revealed a stormy convalescence following previous delivery from below.

In marked disproportion, the case is well made for the woman who can have an elective operation under ideal conditions. It should carry with it no complications. Very different is the woman with a border line pelvis, in whom, in spite of careful examination, there is definite doubt as to the outcome. Here a test of labor may be deemed advisable. If the time honored regulation "test of labor" be employed, it implies 2 hours of second stage pains with a dilated cervix and ruptured membranes. Such "trial of labor," even under the best conditions, is a severe test of cesarean section irrespective of the type of operation employed—under any but ideal conditions it might be highly dangerous.

The observation of the influence of labor for shorter periods may be informative and permit of some differentiation as to the direction which the future course of labor must take—undoubtedly the low cervical operation in some form is best suited to such conditions. It is, nevertheless, true in our own experience that the more closely the trial of labor is made to correspond to what is generally accepted as such, the greater will be the risk to both mother and child, even under the best conditions. While Lawson Tait, in 1895, advocated section in the treatment of placenta previa, it is only of relatively recent date that its value is becoming more widely appreciated. The performance of the operation for the central variety has been practiced much longer than for the less marked forms. The combination of blood transfusion, local anesthesia and cesarean section is in many clinics becoming to be the treatment of preference for not only the central, but many of the lateral, varieties as well. In our series 25 patients were operated upon in this way with no maternal mortality.

Accidental hemorrhage. Of late years the employment of cesarean section in retroplacental hemorrhage has become a more frequent procedure. The situation is very different from placenta previa. Usually one is dealing with the late stage of toxemia. The child often succumbs before any therapy can be initiated and the indication for operation must be purely in the interest of the mother. It is true that in a few instances failure of the uterus to contract, with therefore constant bleeding, might compel one to interfere by cesarean section and possibly a Porro operation, but in most circumstances the more accepted conservative measures will suffice to control the situation. This group is not ideal for any prolonged or severe surgical intervention.

Toxemia of pregnancy and chronic nephritis formed 9.6 per cent of the series. In eclampsia the operation was performed on 5 occasions with 3 deaths. In the pre-eclamptics and chronic nephritics there were no deaths. It is clearly evident that the eclamptics were not well chosen, the disease being very severe in each instance, but the result to some extent was in keeping with experience generally, and confirmed us in the belief that the performance of the operation was an unwise decision. It would seem that cesarean section has little or no place in the therapy of eclampsia when the end-results are contrasted with those now being obtained from palliative treatment, where the mortality is about 5 to 8 per cent.

Adair has demonstrated the value of section in the pre-eclamptic, especially when in addition to toxic manifestations failing to ameliorate under treatment, there may be an associated mechanical lesion. Then, under local anesthesia, the risk seems justifiable.

Any widespread adoption of the operation in the toxic woman, however, must inevitably fail if the usual criteria for surgical healing mean anything.

TABLE II—SHOWING RISE IN INCIDENCE OF CESAREAN SECTIONS

Year	Total deliveries	Class c cesareans	Cervical cesareans	Porro operations	Total cesareans	Incidence of all cesareans per cent	Del. eries per cesarean

it can be associated with disastrous results. Munroe Kerr of Glasgow recorded the results in a series of 220 women operated upon late in labor in which there were 22 deaths a mortality of 10 per cent. When in addition there had been preliminary efforts to deliver from below the mortality quickly rose to 27 per cent.

Table III compiled by Blacker illustrates the results in carefully selected cases.

Aside from the immediate mortality risk there are many points of future importance to the woman which demand careful consideration. The classical and indeed the low cervical operations are frequently associated afterward with varying degrees of infection which influence healing and may leave a weakened scar to offend in future pregnancy or labor. Infection lying dormant may in future cesareans prove to be a grave danger. Perhaps a point of even wider significance is the fact that having launched the woman on a surgical career she will in all likelihood have to continue in this way throughout her entire obstetrical life—surely a matter of some importance to a very young woman. In our series in Montreal there were 123 instances in which section had been performed before (21 per cent of all cases). In this group alone there were 4 maternal deaths, or 3.2 per cent, and 5 fetal deaths 4 per cent. Sparling, in a recent review of 24,856 deliveries in the Royal Victoria Hospital Montreal both in the hospital and dispensary services in a period from 1927 to 1936 found that 562 cesareans had been performed an incidence of 2.2 per cent or 1 in 44.3

deliveries with maternal death rate of 3 per cent, a fetal death rate of 8.3 per cent and a morbidity rate of 61.92. In our clinic a case is considered to be morbid with a temperature of 100.6 degrees on any one occasion during the neonatal period save the first 24 hours.

The accepted indications for cesarean section the world over have always been marked pelvic contraction, cephalopelvic disproportion, obstructions of the birth canal by neoplasms or atresia through the narrowing of the cervix or vagina. Lawson Tait suggested placenta previa and more lately certain toxic states have been included. The apparent safety of the low cervical operation has encouraged the inclusion of many other relative and questionable indications.

In our own series cesarean section was performed in the bulk of the cases for the following reasons:

1. Pelvic contraction or cephalopelvic disproportion
2. Neoplasms obstructing the birth canal
3. Hemorrhage (placenta previa)
4. Toxemia
5. Repeat sections

Although well defined architectural changes in the pelvis govern the performance of the operation in so many instances it is well to recall the experience of Schauta in a large series of 50,000 deliveries in which in 5,283 women varying degrees of disproportion were encountered. In 4,116, or 77.8 per cent spontaneous deliveries occurred with only 4 maternal deaths and a fetal death

SYPHILIS IN THE PREGNANT WOMAN

JAMES R. McCORD, M.D., F.A.C.S., Atlanta, Georgia

IT IS probable that the following statement is too conservative. a woman with a strongly positive blood Wassermann reaction who becomes pregnant and who does not receive antisyphilitic treatment during pregnancy has only about a 35 per cent chance of giving birth to a living, healthy baby. The same woman with adequate treatment during pregnancy has a 95 per cent chance of giving birth to a living, healthy baby.

Rather than try to cover the subject assigned me with a statistical review and a maze of figures, I am going to give you my own opinions of the subject, gathered from an experience of some 3,000 cases.

It seems wise, in the light of present knowledge, to teach that congenital syphilis is always the result of the disease in the mother. In other words, the direct transmission of syphilis from the father to the fetus probably is not possible. The activity of the syphilis in the mother seems to be the determining factor as to whether the fetus will or will not be syphilitic. In so far as I know, there is no sure method of knowing what the activity of the disease is in pregnant women.

The diagnosis of syphilis in pregnant women must, in the large majority of instances, be made from a properly done blood Wassermann test that is positive. It should be emphasized that these tests should be done in well organized laboratories and not in doctors' office laboratories by mildly competent technicians. A positive test that has been properly done means syphilis. Pregnancy does not cause false positive reactions. It does cause many false negative reactions. We have autopsy material in our laboratory in which the organisms of syphilis were demonstrated in 221 abortions and babies at all periods of gestation. One blood Wassermann reaction during pregnancy or at the time of labor was negative in 29 per cent of the mothers. In a recent study of 175 stillbirths (colored) at all periods of gestation, the pathognomonic bone changes of congenital syphilis were found in 37 babies, an incidence of 20 per cent. The maternal Wassermann reaction was negative in 16, an incidence of 43 per cent. This, to me, is a disturbing problem that must

be constantly kept in mind and upon which more work must be done. Repeat Wassermann tests would probably have been positive in some of these women but this cannot always be done. We must be on the alert for such cases and not put implicit faith in one negative Wassermann reaction. Careful histories and physical examinations will, many times, indicate treatment during pregnancy though the Wassermann reaction be negative. In our clinic it is the rule to repeat a positive blood Wassermann test before beginning antisyphilitic treatment. At the present time it is not possible to repeat all the negative tests. Increasing experience has taught us that a weakly positive Wassermann reaction during pregnancy demands careful consideration and means more than in the non-pregnant. It is a safe rule to treat pregnant women with positive blood Wassermann reactions during each pregnancy even though prior treatment has reversed the reaction.

Syphilis is transmitted to the fetus from the mother by the placental circulation. Theoretically, there should be placental syphilis with every syphilitic baby. This is probably true but often not demonstrable.

What do we mean by antisyphilitic treatment during pregnancy? What are its limitations? What are its dangers? When should it begin and how should it be controlled? What results can be obtained?

I think that it is the generally accepted opinion that the basis of such treatment is to prevent syphilis in the baby. Do not attempt to cure the disease in the mother. It is our opinion that some of the serious results that have been reported were caused by neglect of this fundamental principle. Treatment should begin as early in pregnancy as the diagnosis is made and should be continued until labor begins. The treatment should be continuous, mild, and gentle. Moore states that treatment begun early in pregnancy prevents the disease in the fetus and that treatment begun later in pregnancy cures the disease in the fetus. Treatment begun before the fifth month of pregnancy and continued weekly until labor begins practically guarantees the woman a syphilis free baby.

If treatment is started early in pregnancy, an alternating course of arsenic and a heavy metal can be used. Arsenic should be the first and the

Presented in the Symposium on Obstetrics and Gynecology, before the Clinical Congress of the American College of Surgeons, Chicago, October 25-29, 1937

TABLE V—RESULTS OF CLASSICAL AND LOW CERVICAL CESAREAN SECTION

Results	Classical		Low Cervical	
	No	Per cent	No	Per cent
Poor or stormy convalescence	67	26.5	14	13.4
Maternal deaths	9	3.2	4	3.8
Fetal deaths	25	6.1	3	2.8
Maternal morbidity	240	60.0	63	60.0

Repeat sections Previous section accounted for 123 cases, or 21.9 per cent of the entire series. In 1927, 12 per cent of all operations were in women who had previously had a cesarean. By 1936 this figure had risen to 34 per cent. This fact speaks the desirability of using the greatest care in the selection of cases for the primary operation for, in the light of mortality alone, repeat section must be considered in our experience as even more risky than the primary operation.

Even though the low cervical operation be more widely employed than the classical, especially in the cases of relative indication such as placenta previa and granted theoretically that vaginal delivery be safer thereby in later pregnancies, it must be conceded that for one reason or another, experience will show that future pregnancies are likely to be terminated again by section.

THE CLASSICAL VS THE LOW CERVICAL OPERATION

In the Montreal series there were 406 classical and 104 low cervical operations. Table V depicts the results in each group.

The classical cesarean section is satisfactory under ideal conditions such as should obtain in the elective operation. It is technically more easily performed but reveals often the decided disadvantage of imperfect healing and therefore leaves the uterus with a weak scar. It is at a disadvantage in the presence of infection and may be associated with the formation of adhesions leading to bowel obstruction.

The low operation on the contrary while more difficult of execution by reason of its position in the lower uterine segment is obviously a safer operation in that the wound is more apt to heal firmly situated as it is in a quieter sector of the uterus. It is better situated for nature to combat infection and increasing experience is demonstrating that it will more safely allow of future delivery through the vagina.

The surgeon doing the occasional cesarean however, will not find this operation easy of accomplishment.

Perhaps the suggestion of Piper and Bachman of the selection of the lower part of the true uterus for the classical operation may under certain circumstances be useful.

CONCLUSIONS

1 The incidence of cesarean section is too high.

2 While it is admitted that cesarean section for the classical indications of pelvic disproportion or obstruction of the birth canal under ideal conditions, can be made a relatively safe operation it is in actual practice associated with a very definite mortality.

3 The broadening of the indications for the operation has definitely increased the risk for both mother and child.

4 The low cervical operation has tended to decrease the risks in the presence of labor or potential infection, but has not removed them entirely.

5 Many women being subjected to cesarean section today would be more suitably dealt with by more conservative obstetrical measures.

CONFERENCE ON TRAUMATIC SURGERY

INDUSTRIAL MEDICINE AND TRAUMATIC SURGERY

FREDERIC A. BESLEY, M.D., F.A.C.S., Waukegan, Illinois

ON this occasion of the tenth conference on Industrial Medicine and Traumatic Surgery, it would seem fitting to review the progress of the teaching of these very important subjects in our medical schools as such instruction is related to the ever increasing demand for trained men in this branch of medicine

Unfortunately there are only a few schools where the deans and faculties have given any thought to changes in their curricula to meet the rapidly changing conditions demanding trained medical men capable of meeting the requirements of such service as changing conditions are demanding

How many of you have been confronted with the difficulty of securing a younger man for a position requiring the qualifications necessary to deal with industrial diseases and injuries? How frequently are you asked by these younger men where they may go to secure adequate training in industrial medicine and traumatic surgery? There are few such opportunities for securing the desired training, and in visualizing the future it is axiomatic that arrangements must be made to provide this training

A brief analysis of existing conditions as they now prevail in the surgical departments of a majority of medical schools may be enlightening. Within recent years there has been a tendency toward narrower specialization, and the term "general surgery" is rapidly losing its significance and concrete meaning. Formerly the teaching of fractures was done by the general surgeon, but more recently the orthopedist is claiming the bone and joint injuries, and in some institutions the diagnosis and treatment of these lesions are being taught by these specialists. Perhaps this is as it should be. One sometimes wonders how proficient the orthopedist becomes in the recognition and treatment of brain injuries, a punctured lung or an injury to the solid or hollow viscera below the

diaphragm. Can the curricula of the medical schools be arranged so that these subjects may be presented intelligently to the student by the various special departments so that he may acquire a basic knowledge of these subjects, or should there be established a separate department for the teaching of industrial medicine and traumatic surgery—a knowledge of which is becoming more and more important and essential for the medical student because of the increasing number of workers in industry and consequently the larger number of patients affected by the accompanying hazards of centralized industries.

Obviously deans of medical schools and many members of the faculties are not cognizant of, or familiar with, the practical problems that occur in this field of medicine, and it should not be the purpose of such a group as constitutes this audience to indulge in destructive criticism of their teaching methods. Quite the contrary. It is our plain duty to help in every way to clarify the situation and to co-operate with teaching groups in bringing about a more comprehensive course of training in this branch of medicine.

Again may I express my confidence in that group of men, who are known as industrial surgeons, to continue to act as pioneers in blazing the trail for the better teaching of these subjects. They are accustomed to opposition but their characters have been such that they have surmounted these difficulties and established themselves in their chosen field as men of foresight and ability. May I urge them to aid in every way in establishing opportunities for postgraduate training in this department.

This can be done only by the concentration of a large number of cases in one teaching center, and we are not unmindful of the importance of the co-operative influence of large industries and insurance companies in bringing about such a situation.

The American College of Surgeons pledges its efforts in the direction of creating greater opportunities and facilities for the teaching of industrial medicine and traumatic surgery in medical schools and hospitals.

Chairman's address presented in the Symposium on Industrial Medicine and Traumatic Surgery, before the Clinical Congress of the American College of Surgeons, Chicago, October 25-29, 1937

last drug to be used. It is our opinion that arsenic and a heavy metal should be used concurrently if treatment is started late in pregnancy.

Shall arsphenamine or neoarsphenamine be used? It is our opinion that it is better to use the one with which you are the more familiar and can best administer. Either one used in the right way, gives excellent results.

Which metal is to be used, bismuth or mercury?

We prefer mercury for the following reasons although most syphilographers believe that bismuth is of more value in curing syphilis, we should remember that we are not attempting to cure the disease in the mother, we are trying to prevent the disease in the baby. It has been our experience that women will be much more inclined to follow treatment faithfully if there is no discomfort, and mercury surely causes less discomfort than bismuth. We think that mercury is less toxic than bismuth. The toxicity of any drug is to be considered seriously in treating pregnant women. We use two small mercurial inunctions weekly. However, bismuth can be used with the highest authority. After all, there is no quibble as to how to treat. The commandment is treat and treat early continuously and gently.

Mild but unpleasant reactions from arsenical treatment during pregnancy can usually be avoided. Particularly in large clinics time is not taken to explain to the patient what is being done. Treat with the stomach empty and after a mild laxative. Take the blood pressure and examine the urine for albumin before each treatment. Question the patient carefully about any sort of reaction from the last dose. If in doubt play safe and omit treatment until you are sure. Emphasis should be given to the fact that all arsenicals given intravenously must be given slowly. Rapid administration will cause reactions in pregnant women.

Repeat blood Wassermann tests during treatment are not necessary and probably not desirable. Cessation of the treatment because of a negative Wassermann reaction is inexcusable.

Perhaps the general opinion is that cord Was-

sermann tests are of no value. However this is not our opinion. A negative cord Wassermann reaction is of little value in deciding that a baby does not have congenital syphilis. Our experience has been that it is only the occasional baby who has a positive cord Wassermann reaction that does not develop other manifestations of congenital syphilis. We did cord Wassermann tests on 1,372 living babies born of Wassermann positive women. The incidence of positive cord Wassermann reactions in the babies of those women who did not receive treatment was 21.2 per cent. There was a positive incidence of only 2 per cent in the babies of the women who received good treatment. The number of positive cord Wassermann reactions in premature babies was double that of the term babies.

We have reviewed our records of 66 dead babies at all periods of gestation in whom the organisms of syphilis were found and whose mothers had negative blood Wassermann reactions. Cord blood is often difficult to obtain from dead babies and was obtained from only 21 of these 66 babies. Of these, 9 were negative and 12 positive, 57 per cent. Every baby that had a positive cord reaction had the bone changes that we think pathognomonic of congenital syphilis. Seven babies had a negative cord reaction and positive bone changes. Perhaps you do not think that a positive cord Wassermann reaction is of any value. It should at least put you on guard and usually within 4 months or less the blood Wassermann will be positive and you can institute treatment. All babies born alive of Wassermann positive women should be intensively observed and examined with frequent blood Wassermann tests for at least 1 year.

The fact that roentgenograms of the long bones are of great value in diagnosing congenital syphilis is strengthened by the following figures. Roentgenograms of the long bones were made on 56 of the 66 babies in whom the organisms of syphilis were found and 94 per cent showed the characteristic lesions of congenital syphilis.

There seems to be no other disease where preventability is more simple than in congenital syphilis.

CONFERENCE ON TRAUMATIC SURGERY

INDUSTRIAL MEDICINE AND TRAUMATIC SURGERY

FREDERIC A. BESLEY, M D , F.A.C.S. , Waukegan, Illinois

ON this occasion of the tenth conference on Industrial Medicine and Traumatic Surgery, it would seem fitting to review the progress of the teaching of these very important subjects in our medical schools as such instruction is related to the ever increasing demand for trained men in this branch of medicine.

Unfortunately there are only a few schools where the deans and faculties have given any thought to changes in their curricula to meet the rapidly changing conditions demanding trained medical men capable of meeting the requirements of such service as changing conditions are demanding

How many of you have been confronted with the difficulty of securing a younger man for a position requiring the qualifications necessary to deal with industrial diseases and injuries? How frequently are you asked by these younger men where they may go to secure adequate training in industrial medicine and traumatic surgery? There are few such opportunities for securing the desired training, and in visualizing the future it is axiomatic that arrangements must be made to provide this training.

A brief analysis of existing conditions as they now prevail in the surgical departments of a majority of medical schools may be enlightening. Within recent years there has been a tendency toward narrower specialization, and the term "general surgery" is rapidly losing its significance and concrete meaning. Formerly the teaching of fractures was done by the general surgeon, but more recently the orthopedist is claiming the bone and joint injuries, and in some institutions the diagnosis and treatment of these lesions are being taught by these specialists. Perhaps this is as it should be. One sometimes wonders how proficient the orthopedist becomes in the recognition and treatment of brain injuries, a punctured lung or an injury to the solid or hollow viscera below the

diaphragm. Can the curricula of the medical schools be arranged so that these subjects may be presented intelligently to the student by the various special departments so that he may acquire a basic knowledge of these subjects, or should there be established a separate department for the teaching of industrial medicine and traumatic surgery—a knowledge of which is becoming more and more important and essential for the medical student because of the increasing number of workers in industry and consequently the larger number of patients affected by the accompanying hazards of centralized industries.

Obviously deans of medical schools and many members of the faculties are not cognizant of, or familiar with, the practical problems that occur in this field of medicine, and it should not be the purpose of such a group as constitutes this audience to indulge in destructive criticism of their teaching methods. Quite the contrary. It is our plain duty to help in every way to clarify the situation and to co-operate with teaching groups in bringing about a more comprehensive course of training in this branch of medicine.

Again may I express my confidence in that group of men, who are known as industrial surgeons, to continue to act as pioneers in blazing the trail for the better teaching of these subjects. They are accustomed to opposition but their characters have been such that they have surmounted these difficulties and established themselves in their chosen field as men of foresight and ability. May I urge them to aid in every way in establishing opportunities for postgraduate training in this department.

This can be done only by the concentration of a large number of cases in one teaching center, and we are not unmindful of the importance of the co-operative influence of large industries and insurance companies in bringing about such a situation.

The American College of Surgeons pledges its efforts in the direction of creating greater opportunities and facilities for the teaching of industrial medicine and traumatic surgery in medical schools and hospitals.

Chairman's address presented in the Symposium on Industrial Medicine and Traumatic Surgery, before the Clinical Congress of the American College of Surgeons, Chicago, October 25-26, 1937

last drug to be used. It is our opinion that arsenic and a heavy metal should be used concurrently if treatment is started late in pregnancy.

Shall arsphenamine or neoarsphenamine be used? It is our opinion that it is better to use the one with which you are the more familiar and can best administer. Either one, used in the right way, gives excellent results.

Which metal is to be used, bismuth or mercury? We prefer mercury for the following reasons: although most syphilographers believe that bismuth is of more value in curing syphilis, we should remember that we are not attempting to cure the disease in the mother, we are trying to prevent the disease in the baby. It has been our experience that women will be much more inclined to follow treatment faithfully if there is no discomfort and mercury surely causes less discomfort than bismuth. We think that mercury is less toxic than bismuth. The toxicity of any drug is to be considered seriously in treating pregnant women. We use two small mercurial injections weekly. However, bismuth can be used with the highest authority. After all, there is no quibble as to how to treat. The commandment is treat and treat early, continuously, and gently.

Mild but unpleasant reactions from arsenical treatment during pregnancy can usually be avoided. Particularly in large clinics time is not taken to explain to the patient what is being done. Treat with the stomach empty and after a mild laxative. Take the blood pressure and examine the urine for albumin before each treatment. Question the patient carefully about any sort of reaction from the last dose. If in doubt, play safe and omit treatment until you are sure. Emphasis should be given to the fact that all arsenicals given intravenously must be given slowly. Rapid administration will cause reactions in pregnant women.

Repeat blood Wassermann tests during treatment are not necessary and probably not desirable. Cessation of the treatment because of a negative Wassermann reaction is inexcusable.

Perhaps the general opinion is that cord Was-

sermann tests are of no value. However, this is not our opinion. A negative cord Wassermann reaction is of little value in deciding that a baby does not have congenital syphilis. Our experience has been that it is only the occasional baby who has a positive cord Wassermann reaction that does not develop other manifestations of congenital syphilis. We did cord Wassermann tests on 1,372 living babies born of Wassermann positive women. The incidence of positive cord Wassermann reactions in the babies of those women who did not receive treatment was 21.2 per cent. There was a positive incidence of only 2 per cent in the babies of the women who received good treatment. The number of positive cord Wassermann reactions in premature babies was double that of the term babies.

We have reviewed our records of 66 dead babies at all periods of gestation in whom the organisms of syphilis were found and whose mothers had negative blood Wassermann reactions. Cord blood is often difficult to obtain from dead babies and was obtained from only 21 of these 66 babies. Of these 9 were negative and 12 positive, 57 per cent. Every baby that had a positive cord reaction had the bone changes that we think pathognomonic of congenital syphilis. Seven babies had a negative cord reaction and positive bone changes. Perhaps you do not think that a positive cord Wassermann reaction is of any value. It should at least put you on guard and usually within 4 months or less the blood Wassermann will be positive and you can institute treatment. All babies born alive of Wassermann positive women should be intensively observed and examined, with frequent blood Wassermann tests, for at least 1 year.

The fact that roentgenograms of the long bones are of great value in diagnosing congenital syphilis is strengthened by the following figures: roentgenograms of the long bones were made on 56 of the 66 babies in whom the organisms of syphilis were found and 94 per cent showed the characteristic lesions of congenital syphilis.

There seems to be no other disease where preventability is more simple than in congenital syphilis.

not only for the industry as a whole, but for specific types of operations. Through this means the relative degree of hazard in various parts of a plant can be appreciated, and, if there is an effective segregation of occupational groups, a sharp distinction can be made between hazardous and non-hazardous occupations. Moreover, the effect of changes in operating procedure can be recognized. However, the symptomatic and physical signs of dangerous lead absorption, by their very nature, are evident in large part after the fact, rather than before it. Therefore if the occupational lead exposure is of such magnitude as to be capable of producing the more serious manifestations of plumbism, no amount of medical supervision and no quality of medical skill and judgment can be or should be expected to prevent the occurrence of lead poisoning. There are industrial physicians who believe they can anticipate the effects of dangerous lead absorption through the recognition of prodromal symptoms or incipient physical signs of intoxication. Others depend primarily upon early microscopic changes in the blood, of which an increase in the punctate basophilia of the erythrocytes is the most familiar, to give warning of impending saturnism. The usefulness of such measures, when employed with skill and with a background of experience, cannot be denied, but they have serious defects in principle and in practice, the elucidation of which would require prolonged discussion and illustration. Suffice it here to say that they should be employed primarily to demonstrate the existence of significant lead exposure rather than to provide means for avoiding the consequences of dangerous conditions that are permitted to continue.

A digression may here be justified to suggest that it is not the responsibility of the industrial physician to find a means for preventing the occurrence of intoxication among workmen who are known to be dangerously exposed to lead compounds. Nor is it his proper part to cover up the results of careless or unsatisfactory management of a plant and to forestall the worst effects of unsafe working conditions through the exercise of his skill in recognizing the imminence of disability just before it becomes awkwardly apparent. It is rather his function to understand the potential hazards of an occupation, to study and to interpret the consequences of exposure to such hazards, to inform the management, and to serve the employees in so far as they suffer from occupational conditions. Satisfactory exercise of this function requires familiarity with plant processes and operations as well as knowledge of the status of the health of employees. Thus periodic plant

inspections as well as periodic physical examinations are required, and careful clinical investigation of all types of illness is necessary. The periodic examinations should be thorough and detailed in their search for symptoms and signs of incipient intoxication, and should be augmented by suitable hematological studies, the extent and frequency of which should be determined by the severity of the exposure. Under favorable conditions of plant operation this type of supervision, among other benefits, will provide a necessary check upon the adequacy of the means employed to maintain the exposure within the limits of safety.

2. *Determination of the lead content of the air in working spaces.* For a variety of reasons which need not be discussed here, the control of respiratory exposure to particulate lead compounds is the most necessary single requirement for the prevention of occupational plumbism. It is of the greatest importance, therefore, that satisfactory methods be available for the determination of the lead content of the atmosphere of work-rooms, and that there should be acceptable standards by which to gauge the hazard in terms of such determinations. In a very practical sense, both methods and the means for their interpretation have been provided. Concerning the methods, little need be said, in view of the detailed descriptions of standard procedures which are available (1, 2). It must be recognized, however, that these methods have their technical and practical limitations and that they must be carried out intelligently and precisely if they are to yield useful information. Rough estimations of the lead content of the air at ill-chosen points in a plant and at inopportune times can yield only misleading information. As to the significance of the results, Legge and Goadby in 1912 concluded from their studies that if the air breathed "contains less than 5 milligrams per 10 cubic meters of air, cases of encephalopathy and paralysis would never, and cases of colic very rarely, occur." More recent workers have set the threshold value of toxicity at a somewhat lower level (3, 9, 11, 13) and there is abundant direct and indirect evidence for the belief that the inhalation of from 15 to 2 milligrams of lead per day is hazardous and will cause lead poisoning in a considerable proportion of individuals. Obviously, therefore, the lead content of the air breathed by workmen should be kept below this level. Atmospheric conditions in plants should be checked from time to time, and the effect of changes in equipment or in plant operation should be subjected to critical examination.

RECOGNITION AND PREVENTION OF LEAD POISONING

ROBERT A. KEHOE, M.D., Cincinnati, Ohio

IT has long been known that many substances may have a harmless—perhaps beneficial—effect upon the animal organism when absorbed into the body in small quantities, and an injurious or lethal effect when absorbed in larger quantities. With the recognition of the practically ubiquitous occurrence of lead in the soil, in food materials, in beverages, in animal tissues, and in the tissues and excreta of human beings, it has become apparent that lead belongs in this group of substances. The character and magnitude of normal lead metabolism have been described elsewhere (4, 5, 6, 7, 8, 11), and there is no need to discuss them in detail, here, but the practical importance of the facts in relation to the recognition of dangerous lead exposure and to the diagnosis of lead intoxication must be emphasized again and again, until it is fully appreciated.

This is not to imply that the behavior of lead compounds in the animal organism is fully understood, nor that the line of demarcation between safe and dangerous lead absorption is as sharply defined as might be desired. Nevertheless, it is safe to say that the knowledge now available, if applied in controlling lead exposure in industry, would reduce occupational lead poisoning almost to the vanishing point. Moreover diagnostic procedure can now be placed so securely upon a physiological foundation that many of the reasons for previous errors in judgment have been eliminated.

The prevention of lead poisoning in industry depends primarily upon the recognition of dangerous lead exposure. There are few types of occupational lead exposure that offer insurmountable or even difficult obstacles to modern hygienic and engineering safeguards. The ingestion of lead on the part of industrial workers can be, and has been prevented in the main by adequately equipped and supervised washroom, locker room and lunchroom facilities. Successful application of these safeguards requires careful supervision, for they can no more be left to chance or to individual performance than can any other plant procedure that calls for precision. Inhalation of fumes and dust—a much more significant type of

exposure—can be maintained within safe limits by properly designed and carefully operated general and local ventilating devices, augmented as required by intelligently chosen respirators. For a variety of reasons, the latter are less desirable and less dependable than other ventilating equipment, and their effective use demands detailed care and attention on the part of employee and management alike, but there are situations where they can hardly be dealt with otherwise. Cutaneous absorption which is of insignificant proportions in all lead trades except those which involve possible contact with certain highly fat soluble organic compounds such as tetraethyl lead, can also be avoided through the use of impervious coverings for the skin. In short dangerous lead exposure can be eliminated provided it is recognized as such and provided there is an adequately directed and sustained effort to do so.

There are, of course, inherently dangerous occupations in trades in which lead compounds and other poisonous materials are handled. Accidents and unforeseen operating difficulties inevitably produce serious hazards from time to time. These can be reduced to a minimum only through the exercise of skill and foresight, and they may be regarded with some degree of philosophic complacency as the natural consequence of the activities of a highly inventive and industrialized population. Although the frequency and the seriousness of such occurrences are likely to bear a fairly direct relationship to the degree of complacency with which they are accepted, they are not of primary importance in the lead trades. In such trades the factor of safety over any considerable period of time depends upon the magnitude of the lead exposure associated with the average normal operating conditions in the plant. The real problem, therefore, consists in knowing the magnitude and the hygienic significance of this basic or ordinary exposure.

Three general methods are available for the recognition of hazardous lead exposure. No one of these methods is wholly adequate for the purpose, but each has a practical and useful place in a successful scheme of plant control.

1. *Medical supervision of workmen.* A carefully maintained clinical study of the population of a plant or an industry will serve to establish the significance of the exposure to lead compounds.

3. *Measurement of the lead excretion of exposed workmen* Studies of the lead excretion of workmen with various types and degrees of lead exposure have shown a definite correlation between the rate of lead excretion and the severity of lead exposure (9-11). The alimentary lead output of persons exposed to particulate atmospheric lead consists largely of that which has been entrapped in the upper respiratory passages, swallowed, and passed through the alimentary tract unabsorbed. Thus the analysis of suitable fecal samples obtained from workmen who represent the various occupations of a plant will give a cross-sectional picture of the exposure associated with their work for the day or 2 days immediately preceding that on which the samples were obtained. The lead content of adequate samples of the urine of these workmen will show the general magnitude of their lead absorption over a considerable period of time. The combination of these data will portray the lead hazards of a plant in terms of the physiological response of the persons who have been exposed to these hazards.

From the viewpoint of the physician, the advantages of this type of information are obvious. The presence of lead in the environment of a worker in atmosphere or otherwise, may or may not be important, but the presence of abnormal quantities of lead in the body of a workman is always important and must be explained. It matters little whether the particles of lead compounds suspended in the atmosphere of a plant are large or small, soluble or insoluble; that the atmospheric lead content is said to be within safe limits or that respirators are believed to be used correctly and faithfully or that other hygienic regulations are believed to be observed adequately, if the men are found to be absorbing significant quantities of lead in the course of days or weeks or months of work. On the other hand, if their lead excretion remains within safe levels, groups of men whose occupational exposure is potentially dangerous may be known to be working in actual security. Moreover the same analytical facilities that furnish information as to occupational lead exposure will aid effectively in the prompt solution of diagnostic problems. An analysis of a sample of blood and a sample of urine may disclose the occurrence of a wholly unexpected episode of lead intoxication, or it may rule out lead absorption and thus lead to the recognition and proper treatment of some other disorder (10).

It may appear that a study of the rate of lead excretion of representative workmen in a lead trade is an impractical means of plant control, and that this type of work should be devoted, pri-

marily, to the accumulation of scientific information. Actually, some experience with the difficulties encountered in industrial practice has convinced me to the contrary. It is especially difficult to interpret minor and incipient ailments and to handle them and plant problems that arise from them, with such assurance and sound judgment as will promote and merit the confidence and co-operation of both workmen and management. Errors in judgment are inevitable unless one has the best available means for testing his conclusions and such errors may be costly far beyond their immediate and tangible consequences. Moreover, it is not easy to demonstrate the need for preventive measures, which may add appreciably to the manufacturing costs of an industry without evidence which is comparable, in its applicability and its precision, to that habitually required by technical men and industrial executives in justification of major expenditures. Such evidence can best be provided by data on the extent of the lead absorption and excretion of exposed workmen. This is not to imply that measurements of the lead content of the air of workrooms are not useful, but rather that they are less useful, especially to the physician, than information derived from the actual study of the plant population.

It is not the purpose of the foregoing paragraphs to present a comprehensive and detailed program for hygienic control in industries in which lead exposure occurs. Neither are they designed to urge the adoption of any one measure for the recognition of significant lead exposure. The seriousness of the problem of occupational lead poisoning in present day industrial activities, and the difficulties associated with the maintenance of safety in potentially hazardous occupations, do not warrant any undue enthusiasm or professional predilection for any one method. Industry needs intelligent and skillful medical supervision, the most satisfactory methods for the recognition of dangerous lead exposure and the most effective technical devices for the maintenance of such exposure within safe limits. In short it will require the combined application of the best available chemical, toxicologic, and engineering facilities to provide an adequate solution of this hygienic problem.

and suture are indicated in such wounds. It may be necessary to include the rib above and the rib below the wound in the sutures in order to maintain approximation. Hemorrhage from the intercostal and mammary vessels may require exposure and ligation, and it may be necessary to encircle the rib with the suture, both distal and proximal to the wound, to control bleeding.

Lacerated and contused wounds of the lung and gunshot wounds that involve the periphery of the lung do not require special treatment except the treatment of hemothorax, pneumothorax, and traumatic empyema, which will be discussed later.

Stab wounds, if sucking in character, are closed by suturing the injured lung to the parietal pleura following the method of Stenbuck and Connors. If near the margin of the sternum and if the pleural space fills rapidly with blood, the wound is explored and the blood vessels are ligated and the suggestions of Stenbuck and Connors are carried out.

Pneumothorax may be of all degrees from a slight amount of air which is absorbed rapidly, to a tension pneumothorax resulting from a valve-like wound sufficient to displace the mediastinum and gravely embarrass respiration. The most dangerous type is that resulting from rupture of the lung without any demonstrable injury of the rib cage.

Tension pneumothorax must always be suspected if cyanosis occurs early and may be diagnosed by bedside roentgenographs. Such patients often have multiple injuries, and a fractured skull or a distended, tense abdomen may claim the surgeon's attention. If the percussion note causes even the slightest suspicion of pneumothorax, a needle should be inserted. First rule out diaphragmatic hernia by roentgenograph, then if air is encountered under tension, leave the needle in place with a rubber tube leading over the side of the bed with the end of the tube placed under water, 2 or 3 feet below the level of the chest. Occasionally pneumothorax is bilateral. Dyspnea and cyanosis always call for action, and a roentgenograph of the chest.

Hemothorax follows all injuries to the thorax in some degree. If the bleeding is from the chest wall, the intercostal vessels, the internal mammary, or the azygos veins have been injured. Hemorrhage is the most common cause of death during the first 24 hours. If the wound is near the sternum or in the region of the posterior angle of the ribs, inspection of the wound and ligation of the vessels may be necessary. If shock is extreme and any operative procedure is contra-

indicated, a small proctoscope may be inserted through the wound and a gauze pack inserted, and pulled tightly against the internal surface of the chest wall to control the hemorrhage. If the bleeding is from a lung, the compression produced by hemothorax and pneumothorax usually is sufficient to control hemorrhage, particularly if the bleeding is from the periphery of the lung. If large hilar vessels or mediastinal vessels are injured, death occurs early.

The blood removed from the pleural space, unless macroscopically contaminated, may be filtered and an autotransfusion performed. The blood in the pleural space tends to become defibrinated by the churning of the lung and does not clot readily.

There is some difference of opinion as to the correct time to remove blood from the pleural space. Undoubtedly the best plan for those not familiar with chest surgery is not to aspirate the blood unless it is disturbing respiration to the point where relief is required. The blood may be safely aspirated 3 to 5 days following the accident. Cultures should be made and if infection is present then one of 3 courses may be followed:

1. Thoracotomy and removal of all clots from the pleural space, flushing with Dakin's solution or some other mild antiseptic solution, and closure of the wound without drainage, to be followed by frequent aspirations.

2. Closed tube drainage and tidal irrigations

3. Daily aspiration and, as soon as frank empyema develops, resection of a rib and institution of closed tube drainage. The first procedure, if done promptly and thoroughly, undoubtedly prevents many contaminated collections of blood from becoming empyema.

Diaphragmatic hernia may be operated upon much earlier than is the practice in most clinics. As soon as the patient has become adjusted to the changed condition, when the shock has subsided and the body fluids have been replaced, the hernia may be repaired. If organization of adhesions and atrophy of the flaps of the diaphragm have taken place, the procedure is much more difficult for the surgeon and far more trying for the patient. Crushing of the phrenic nerve on the side of the hernia is a valuable pre-operative procedure.

Traumatic subcutaneous emphysema usually does not require treatment other than the occasional release of tension as near to the injured rib as possible, or the passage of a moderate size needle into the chest and the release of air from the pleural space. Very occasionally it may be necessary to suture a rent in a lung or remove a fragment of the rib from the lung.

INJURIES OF THE CHEST AND ABDOMEN

EDMUND BUTLER MD, FACS, San Francisco California

A RELATIVELY high percentage of the fatal accidents occurring in industry and in transportation results from injuries of the chest and of the abdomen, and their various complications. The immediate result of an injury of the chest may so embarrass the vital functions of respiration and circulation that death may occur within a few minutes and many accidents result in such extensive injuries that death results regardless of treatment. Judging from the records of autopsies some of our traumatic surgeons are of the opinion that about 10 per cent of the deaths which resulted from chest injuries might have been prevented.

Our automobile manufacturers spend large sums in the investigation of accidents and in the means of preventing them. The present automobile steering wheel is so designed that it crumbles into small pieces or bends when struck forcibly by the body of the driver. The old wooden steering wheels and wooden spiders were a constant menace, and caused many puncture wounds of the chest and abdomen. Similarly the development of shatter proof glass and other new features of modern automobiles have been designed with safety as the objective.

The more common injuries and their complications are (1) fractures of the bones of the thoracic cage (2) contused and lacerated wounds of the lungs (3) contused and lacerated wounds of the chest wall (4) gunshot wounds and stab wounds of the chest (5) pneumothorax (6) hemothorax (7) diaphragmatic hernia (8) traumatic subcutaneous emphysema, (9) traumatic empyema (10) pulmonary abscess.

The less common injuries and their complications are (1) cardiac contusion and laceration (2) hemopericardium (3) traumatic chylothorax (4) gangrenous pneumonia.

Undoubtedly pleural reflex and air embolism result from injuries of the chest but those conditions will not be discussed in this paper.

The two symptoms of greatest importance are dyspnea and cyanosis. Shock of an alarming character occurs following most injuries of the chest. Unless dyspnea or cyanosis develops along

with the shock, the outcome usually is favorable. A certain degree of shock is desirable. While the shock is present the hemorrhage from the injured soft parts often subsides and remains controlled unless too active therapy is instituted. Intravenous administration of fluids and therapeutic agents which raise the blood pressure are contra-indicated. Primary shock undoubtedly is one of the very best friends of the surgeon and the injured individual. This is not true of the long continued primary shock or of the prolonged secondary shock. Shock is the attempt on the part of the organism to control hemorrhage and were it not for this phenomenon, exsanguination would result from an injury of a small artery or a slight laceration of the lung, of the liver, spleen or kidney. Normal saline solution administered intramuscularly, heat, relief from pain and the Trendelenburg position are indicated as a safe routine of treatment.

In caring for fractures of the bones of the thorax there are 3 conditions which require special attention.

1 Depressed ribs, especially if the fragments are driven into the lung. The depressed portion of the chest must be elevated, and usually that is sufficient to release the lung. Under local anesthesia or often without any anesthesia the ribs may be grasped with towel clips and pulled into position and maintained there if need be by attaching towel clips to a weight hung over the side of the bed.

2 The sternum may be fractured free from all of the ribs and on inspiration be depressed thus interfering with both respiration and cardiac action. The sternum may be grasped with towel clips, or a screw may be inserted into the central portion and the sternum be held in position manually or by a weight attached to a frame over the bed or to a metal or wooden cradle placed over the chest.

3 A section of the rib cage may be fractured anteriorly and fractured posteriorly and the intermediate portion of the chest wall become depressed during inspiration. This condition requires traction in the same manner as previously described.

Lacerated wounds of the thoracic wall, if sucking in character, must be closed by strapping with adhesive over moist towels. Early debridement

From the Department of Public Health, San Francisco and Department of Surgery, Stanford University Medical School. Presented at the Symposium on Industrial Medicine and Traumatic Surgery before the Clinical Congress of the American College of Surgeons, Chicago, October 23-29, 1937.

cent of these patients. When the shock is severe, an extremely painful injury, severe crushing injuries, and hemorrhage are responsible. Shock is very slight and often is absent in the solitary ruptures of the intestine or of the urinary bladder.

2. Vomiting is frequently not present and seldom contains blood. Vomiting often is delayed until septic peritonitis has developed.

3. The pulse is quickened; when extremely fast it indicates hemorrhage. The rapidly rising pulse rate and the falling blood pressure indicate active hemorrhage.

4. Temperature is normal or often subnormal immediately after an accident.

5. Respiratory movements of the abdomen may not be restricted, and the thoracic type of respiration often is delayed until contamination is general or until septic peritonitis has ensued. In ruptures of the stomach and upper intestine, the contents are very irritating, and a scaphoid, rigid abdomen and thoracic type of respiration are found immediately on examination. The contents of the colon are much less irritating and the spread is relatively slow. Distention is not present until late when peritonitis has caused paralytic ileus. Peristalsis may not be changed at first, but usually is restricted.

6. Rigidity may be absent, particularly in this true in injuries of the lower bowel and ruptures of the bladder. Peritonitis confined to the true pelvis usually is associated with very slight abdominal rigidity because of no parietal peritoneal involvement. The contents of the lower bowel are less irritating than those of the stomach and duodenum.

7. Local tenderness is not remarkable earlier and often is demonstrable only by rectal examination and by percussion.

8. Localized dullness, when present, indicates a confined hemorrhage in the mesentery, in the omentum, or in the retroperitoneal area. Free blood in the peritoneal space seldom is demonstrable even when a considerable quantity is present. A feeling of soft resistance by rectum will be given by a collection of blood in the pelvis.

9. The absence of liver dullness is not a reliable sign for pneumoperitoneum, but a tympanitic area above the liver in the midaxillary line and below lung resonance is indicative of pneumoperitoneum.

10. Rectal examination must never be omitted, early peritoneal tenderness may be elicited only by rectum. In retroperitoneal ruptures of air-containing viscera, emphysema of the pelvic cellular tissues may be palpated. In one patient a retroperitoneal rupture of the duodenum produced

pelvic emphysema, easily palpated by rectum, when the patient was first examined 17 hours after the accident.

11. Pain is the most important symptom and is present in some degree in all conscious patients. Constant, although perhaps very mild at first, it tends to increase gradually. Such pain sometimes is referred to the back and to the supraclavicular triangles when the peritoneum of the diaphragm is irritated. Following retroperitoneal rupture of the duodenum, there is pain in the back and in the testicles. With rupture of the bladder there is pain across the lower abdomen which seldom is severe and often is mistaken for the pain that is believed to result from contusion of the abdominal wall.

12. Frequent, complete blood examinations must be made. Slow, continuous bleeding soon shows a reduction in the red blood cell count and in the hemoglobin. Such changes often show in as short time as 1 or 2 hours. Bleeding in any space or in any tissue causes leucocytosis, often as much as 30,000 to 60,000 white blood cells. In shock, the peripheral concentration of blood gives a high red blood cell count and a high hemoglobin index.

13. Roentgenographs of the abdomen are indispensable. Ruptures of the diaphragm, blotting out of kidney shadow by hemorrhage, pneumoperitoneum, and emphysema of the posterior abdominal wall are conditions which may be revealed. It is well to have one film with the patient sitting up or at least turned on the side. Neopex injected intravenously may help locate the injury in the kidney, along the ureter, or in the bladder, and may indicate the extent of the injury. Also it may demonstrate which kidney should be explored when contusions are bilateral and either kidney may have been injured.

Diagnosis is always difficult in the patient who is most helped by intervention. Frequent examination and rechecking of the findings and of the laboratory work are essential if the best results are to be obtained. Continuous abdominal pain and increasing tenderness must not be relieved by sedatives without a full realization of the conditions which may be causing the distress.

The prognosis in all abdominal injuries is grave. Pollard reported 56 cases of which 17.85 per cent died within the first 5 hours, 32.14 per cent died within 5 to 25 hours, 33.94 per cent died within 24 to 48 hours, 16.07 per cent died within 3 to 16 days. This latter group of 16.07 per cent contains the patients in whom we are most interested. Surgical intervention, early, in these patients may be rewarded by many recoveries. In this

Pulmonary abscesses following stab or gunshot wounds are drained easily if the treatment as outlined by Stenbuck and Connors has been instituted. Following their procedure general empyema is much less likely to occur.

Cardiac lacerations necessarily require early treatment. Most cardiac lacerations produce death before the patient arrives at the hospital, but in patients where the injuring instrument has also torn the pericardium so that the blood escaping from the heart freely leaves the pericardium and enters the pleural space recovery may follow exploration and suture. Mattress sutures of fine Pagenstecher material are most useful, as Pagenstecher material is handled and tied easily. Even though suturing is successful a high percentage of heart wounds terminate in death from infection.

Hemopericardium usually is not seen sufficiently early to be relieved. Roentgenograms give us our best and earliest evidence. Occasionally when there is gradual oozing from the chest wall or from a small vessel on the surface of the heart aspiration will benefit and exploration and hemostasis may be indicated to control the hemorrhage. In traumatic chylothorax, aspiration usually is all that is indicated.

Gangrenous pneumonitis usually is fatal, but if only a small portion of the lung is involved drainage and removal of the separating slough may bring about recovery.

The diagnosis in all of the conditions mentioned is dependent upon careful examination, and the proper evaluation of the findings. Most of these patients have other injuries, of head, abdomen, or extremities. It is almost impossible to be certain of any physical findings. The recent refinements in the portable roentgen units have been most valuable to the traumatic surgeon. Excellent films may be made at the bedside and many of the conditions that were merely suspected are now diagnosed early. A drop in the mortality rate is certain to be the result.

Tetanus antitoxin and a full therapeutic dose of polyvalent anaerobic serum should be given in all lacerations of the chest and lung.

INJURIES OF ABDOMINAL VISCERA

The remarkable fact of the absence of all symptoms indicating a mortal injury for up to and of 2 hours' was the observation of Pollard in 1858. This observation is still timely and to be borne in mind when caring for the present-day industrial accident and the auto accident injury. We should always remember that the 2 hours may be lengthened to 6 or 8 hours under conditions of shock and alcoholism.

Surgical intervention often is delayed because of the following factors:

- 1 The injury does not seem serious to the patient and the medical advisor is not called until hours or even days following the accident.

- 2 The frequent absence of visible evidence of injury of the anterior abdominal wall leads the patient and the doctor to disregard the early mild symptoms of perforation of a hollow viscus.

- 3 The symptoms at the first examination are not remarkable, and frequent observations and examinations are not made.

- 4 Shock and alcoholism interfere with the usual reactions to serious injury on the part of an individual.

Battle, in the *Lancet* of 1919, made this pertinent statement: "It requires firmness to induce the patient to submit to an operation before peritonitis has made the need for operation obvious to the patient's friends." Vance stated, "Injury to the hollow viscera is often solitary, and complications develop insidiously. Death is from peritonitis rather than from hemorrhage."

The frequency of the injury of intra abdominal viscera during the pre automobile period given by Makins in 1899 was: kidney, 39+ per cent, intestine, 23 5+ per cent, bladder, 5+ per cent, mesentery, 3+ per cent.

Pollard located the injuries of the intestinal tract in 123 cases: duodenum, 6 cases, jejunum, 44, ileum, 38, mesentery 31 and colon, 4. Fifty eight per cent of the injuries were in the first 3 feet of the jejunum and the terminal 3 feet of the ileum. Bacon and Le Count reviewed 384 autopsies: all automobile accident injuries, and found the liver involved in over 50 per cent.

The viscera may be injured in the following manner:

- 1 Crushing of the viscus between the offending instrument and the bodies of the spine or other parts of the skeleton.

- 2 A tangential force moving the bowel beyond its limits of mobility may result in tears of the mesentery and tears in the intestine near the fixed portion.

- 3 Compression of fluid or gases in a single loop of intestine or in the bladder, which forces the wall to give way at the point of least resistance.

- 4 Fragments of the pelvic bones may rupture the bladder or the rectum.

- 5 Compressed air or water under pressure entering the anus may produce rupture of the rectum of the colon or of the stomach.

Symptoms. In the presence of abdominal injury the following symptoms are mentioned:

- 1 Some degree of shock is present in 80 per

ent, and exploration should be performed if these symptoms persist.

Surgical intervention in many of these patients cannot be considered. The injuries are extensive and multiple and the shock is extreme. Many come out of the shock under proper treatment and become fair operative risks. The high mortality must not close our eyes to the few who recover following surgical intervention. Builly reported the first operation for rupture of the intestine in 1883. The first successful operation was reported by Moty in 1889.

In exploration of the abdomen, complete relaxation on the part of the patient and an ample incision are essential. If free, uncontaminated blood is encountered it may be dipped out with a small ladle or aspirated, citrated, and run back into the patient's vein. Autotransfusion is a very valuable procedure. The small intestine is to be inspected carefully in a systematic way beginning at the duodenojejunal angle and proceeding to the ileocecal valve. It is very easy to overlook small perforations, so it is always well to instruct nurses as well as the assistants to watch closely. The stomach and colon are to be examined. Ruptures of the stomach are usually in the anterior wall and are easily found. Rupture of the duodenum is infrequent but swelling, bile discoloration, and emphysema in the region of the duodenum indicate a retroperitoneal rupture. The duodenum is easily mobilized by cutting the peritoneum to the right of the descending portion and rolling the duodenum to the left. If a retroperitoneal tear is present it is easily found and sutured.

An unusual rupture of a hollow viscus following crushing injury of the abdomen is a tear in the anterior wall of the rectum. The crushing may have been in the upper abdomen and the tear a

result of explosive forces produced by the compression of the gases in the lower colon. Such a condition was found in 2 patients, in 1 it was found during autopsy, and in the other it accompanied a rupture of the small bowel. Both latter injuries were repaired and this patient recovered.

The method of closure of any rupture of the intestine is not so important as long as the bowel is not constricted and there is not great tension on the sutures. Most openings in the small bowel are closed transversely. A double row of plain No. 0 catgut sutures are used in the bowel and the stomach, and three rows in the bladder. If there are many holes in a single loop, resection is simpler, and lateral anastomosis is always preferred.

Suprapubic drainage is always instituted in rupture of the bladder. If the extraperitoneal tears are small, free suprapubic drainage will prevent extravasation, and suture is not necessary.

The peritoneal space is never drained. It is almost impossible to establish peritonitis experimentally in animals unless some foreign material is left in—and a drain is foreign material. Multiple drains do not prevent general peritonitis but tend to provoke localized peritonitis and many adhesions. When the colon is ruptured retroperitoneally, a drain is always inserted into the retroperitoneal cellular tissues.

It is obligatory that all patients who have been through a serious accident be looked upon as seriously injured. The diagnosis may be made if we use all the diagnostic aids at our disposal and do not fall into the habit of pronouncing finally following one examination, and that examination made shortly after the accident. More and more are we becoming dependent upon the x-ray department for help in the early diagnosis of injuries resulting from trauma.

group are included the small perforations the mesenteric tears because of which the intestine later may slough, the contusion of the bowel which later produces slough, the ruptured urinary bladder, and the ruptured spleen and kidney.

Curtis in 1887 remarked, "Recovery after a rupture of the intestine is a surgical curiosity." The same year Curtis conducted 44 experiments in which the abdomens of anesthetized dogs were contused with the following results: 13 lacerations of the mesentery severe enough to deprive the intestine of its blood supply, 16 contusions of the bowel without perforation but likely to slough later, 8 ruptures of the bowel, 2 of which were multiple. The danger from mesenteric tears is not generally appreciated. Such patients are observed until the bowel sloughs and peritonitis develops before intervention is considered. Disturbances in the blood supply from the mesenteric tears, not extensive enough to cause sloughing, may produce lymph stasis and round cell infiltration of the bowel, followed by fibrosis. Such fibrosis producing partial or complete obstruction, possibly explains some of the conditions diagnosed as cicatrizing enteritis.

Rupture of the liver, of the spleen and of the kidney always must be suspected following an injury where great traumatizing force has been expended. An injury of the kidney may be slight such as subcortical tears or contusions producing a few red blood cells in the urine. The increase of pain in the flank and the persistence of bloody urine should suggest that a laceration of the kidney may be present. Perirenal hemorrhage usually displaces the ascending or descending colon toward the midline. If the bleeding continues and the patient shows evidence of blood loss exploration of the kidney is imperative. When it is difficult to rule out intra abdominal injury exploration through a transverse incision beginning at the edge of the rectus muscle and extending into the flank is the incision of choice. It is very easy to remove a kidney through this type of incision. The kidney is retracted toward the abdominal aorta, tending to relax the pedicle rather than away from it as in the nephrectomy, through a posterior incision. Following the removal of one kidney I have been rather reluctant to give a transfusion because anuria has occurred twice following such transfusions.

Rupture of the urinary bladder happens much more frequently than is generally believed. Rupture may cause few symptoms and in the presence of multiple injuries of the soft tissue or injury of bone is so easily overlooked. It is an order in the San Francisco Emergency Hospital Service that

every deeply alcoholic or shocked patient who comes into the hospital shall be catheterized as soon as possible. Less than 5 per cent of the ruptures of the bladder are caused by fractures of the pelvis and 40 per cent result from automobile accidents. The remainder are produced by crushing injuries and falls.

It is not unusual to inject 300 cubic centimeters of saline solution into a bladder which has been ruptured and remove 700 cubic centimeters or more of fluid. In such patients the catheter sticks through the rupture in the bladder and siphons out urine and saline which are free in the pelvis. Several patients have voided bloody urine when roentgenographs showed that urine was free in the peritoneal space. The test that should be used in all of these patients is this: if the urine contains blood or no urine is removed by catheter, inject 500 cubic centimeters of 5 per cent sodium iodide solution, and make a roentgenograph. This will show if the solution is confined in the bladder. Air may be found under the diaphragm if there is an intraperitoneal rupture of the bladder and air has been injected into the bladder. Five to 8 hours after injury the bowel, omentum or the edges of the wound may adhere closing the bladder temporarily, and thus the sodium iodide may be confined to the bladder.

The treatment of rupture of the liver if it is possible to rule out rupture of the kidney and of the spleen, is expectant. Bleeding from large lacerations of the liver may cease if the patient is allowed to remain in a state of low blood pressure and complete rest. Intravenous administration of fluids, heart stimulants, and agents which raise the blood pressure are contra-indicated. If exsanguination is imminent, blood transfusion must be performed. If exploration is performed bleeding from the liver may be controlled by compressing the hepatic artery and the portal vein in the gastrohepatic omentum between the index finger and the thumb with the index finger in the foramen of Winslow. A springy gastro-intestinal clamp the blades guarded with rubber tubing may be used for compression of these vessels.

Unless the spleen is comminuted, hemorrhage is slow and often 3 or 4 days pass before exsanguination is threatened. The leucocytosis upper abdominal distress pain in the supraclavicular regions and the constant drop in hemoglobin should suggest intra abdominal bleeding. The rhythmic contractions of the spleen squeeze out the clots and thus cause recurrent hemorrhage. Tears in the mesenteric vessels are difficult to diagnose but the signs of intra abdominal hemorrhage and continual abdominal distress are pres-

centralized first aid stations or dispensaries are desirable in order to insure adequate treatment and records

When hospital services are needed by an industrial organization it is urged that it draw upon existing facilities for such service wherever possible. Very few sections of the country at the present time are so remote as to be inaccessible to an approved hospital. Industrialists will find that in the long run they can obtain more efficient hospital service at less cost from organizations whose sole purpose is to conduct hospitals than they could by establishing their own hospitals

SCOPE OF THE MEDICAL SERVICE

Half-way measures will bring only partial results. On the other hand, a too extensive medical program may be so burdened with unnecessary frills and unappreciated paternalism that the end-results will not justify the costs. The following outline for the scope of an industrial medical service has been proved effective and adequate in many industrial organizations and its further adoption is urged:

1. *Pre-employment physical examinations* The purpose of pre-employment physical examinations is to ascertain the physical status of prospective workers in order to facilitate the placing of such workers in positions for which they are best or at least suitably fitted. These examinations should be made of all, regardless of whether they are office or shop workers. The examinations should be made only by qualified medical examiners and the records thereof should be filed in the medical department under medical supervision and not in the employment department. A few employers are still using lay attendants for making physical examinations of employees. The folly thereof is evident.

The question of doing routine Wassermann or Kahn tests on all new employees is now a current one. Some of the large industrial organizations are making such tests just as much of a routine procedure as is the use of the stethoscope in examining the heart. Workers, whether new or old, who have syphilis are usually permitted to work in either selected or their usual positions provided they are receiving adequate treatment.

The principle involved in taking an inventory of the human machine before employment is sound. When properly done, it is profitable to employer and to employee, and within the next 5 to 10 year period pre-employment physical examinations will no doubt become a standard practice for all industrial organizations. After reviewing thousands of physical examination

record forms used in industry, the College has recently formulated a short series of such record forms which provide space for recording the essential data that are desired. Samples of these record forms may be obtained by writing to the American College of Surgeons.

2. *Periodic health examinations.* The purpose of periodic health examinations is to aid in maintaining the health of the worker and to further assure the compatibility of placement with the health of the worker and with the safety of others. Obviously these examinations should be done with sufficient thoroughness and frequency to permit of accurate diagnosis and early recognition of disease if the objective of "health maintenance" is to be accomplished.

A number of industrial organizations examine annually all of their employees from the plant manager down to the watchman at the gate, with more frequent examinations given to those who are exposed to occupational disease hazards. Others examine annually all of their employees over 45 years of age and every 2 or 3 years those under 45. Still others have placed the health examinations on a purely voluntary basis. Experience has shown that this latter practice is not as efficient as in those instances in which an orderly system plus voluntary examinations has been provided.

The industrial physician should serve as an unbiased but friendly counsellor to the employee, referring those who are found to have physical defects to their own private or family physician for treatment or follow up. Industrial physicians should never solicit private patients from among the workers whom they serve in the plant. To do so would not only be unethical but it would betray the employer and destroy the confidence of the employee in the medical service. Physicians should obtain their patients on merit alone.

The industrial physician by serving as a liaison between the employee, the employer and the private practitioners can create an alliance among the interested groups that will allay criticism and make preventive medicine more effective than any other procedure. Such an opportunity for preventive work should not be impeded.

3. *Prevention and care of all industrial injuries and occupational diseases.* The physician in charge should determine the presence or absence of occupational disease hazards in the plant. The services of a chemist or a laboratory worker may be required in order to determine the degree of the health hazard but the engineering department is charged with its control. Every effort should be made by the industrial physician to co-operate

THE MODERN CONCEPT OF THE INDUSTRIAL MEDICAL PROBLEM

M N NEWQUIST, M D, Chicago Illinois

THE industrial medical problem has been and always will be fundamentally the same, namely, 'the adequate care of the health of the industrial worker'. Lack of information on the subject, lack of interest on the part of some employers, and inadequate workmen's compensation laws have been important factors in retarding a more widespread realization of what constitutes adequate care of the industrial worker's health. While the machine age and the more widespread use of toxic substances or processes in industry have made the health problem more complex, nevertheless the objective of maintaining the health of the worker has always been the same and the attainment of that objective should never permit of compromise.

ATTITUDE TOWARD THE PROBLEM

The defensive type of industrial medical service designed mostly to protect the employer and the purely curative type of service which were so prevalent in the past are fortunately fading out of the picture. Activated by costly experiences with industrial injuries and occupational diseases in the past, obligated by compensation laws which are gradually including occupational diseases, and enlightened more recently by publications and symposia on occupational diseases which have been held throughout the country, there seems to have been a general and more thorough awakening of employers and of the medical profession to their responsibilities for the care of the health of the industrial worker. There still are a few diehards, of course who have closed their eyes to occupational disease hazards in their plants or who do not report disabilities resulting therefrom simply because their state has not yet recognized occupational disease in their compensation law.

Many employers, however, have had a change of attitude. They are adopting a broader view point of the whole subject and are manifesting more of a protective interest in the health and working conditions of their employees. This is as it should be. Another encouraging situation is the fact that industrialists are now realizing that they

cannot cope with the employee health problems alone. Similarly the members of the medical profession are aware of the lack of sufficient scientific knowledge in regard to the toxicology of certain industrial materials and of the fact that further research in this field is required. With a co-operative attitude on the part of the employer, the physician or surgeon, the laboratory worker, the engineer and the worker himself the problems of occupational disease and health maintenance will be no greater than the control of the situation with respect to industrial injury in which so much progress has already been made.

ORGANIZATION OF THE MEDICAL SERVICE

Personnel. To secure the most efficient type of medical organization the industrialist should first of all employ a competent medical or surgical director. The management and the medical director together can formulate more practical policies and procedures for their health program than would result from independent action.

Co-operative interdepartmental working relationships should of course be established but the authority and responsibility for the selection of the first aid and medical personnel and for the direction and supervision of the medical service should be delegated to the medical or surgical director. Given these responsibilities, the medical director should then be expected to exercise his prerogatives and to produce results. Fixing the responsibility for the supervision of the medical service in competent medical hands and at one point is the most important step in the organization of the medical service. With this done accomplishment of the objectives is largely assured.

Obviously only competent medical and surgical assistants and consultants should be selected. The first aid attendants should be properly instructed and trained in their duties and their work closely supervised.

Facilities. The use of first aid kits in extremely decentralized industrial operations may be necessary but their unsupervised use in industrial establishments as a whole should not be permitted. Experience has shown that such use will bring more harm than good. Fewer and more

TABLE I.¹—ACCIDENTAL DEATHS IN THE UNITED STATES IN 1936

Total	111,000
Home	38,500
Motor vehicle	37,800
Public (not motor vehicle)	20,000
Occupational	18,000
Disabling injuries	10,750,000
Wage loss, property damage, medical expense	\$3,700,000,000

¹National Safety Council report

workers of \$2,000,000,000 per year at a wage rate of \$5 per day.

Respiratory infection (the common cold) is still the greatest cause of absenteeism. Since much of the absenteeism in industry is preventable, we then have additional tangible objectives toward which an industrial health program should be directed.

Accident fatalities There were 18,000 occupational deaths in 1936 as compared with 16,500 in 1935, an increase of 9 per cent. Death totals as caused by types of accidents, number of disabling injuries, and related costs are given in Table I as reported by the National Safety Council

MEDICAL AND COMPENSATION COSTS

In a study of medical costs made by the College, 299 industrial organizations representing 1,237,775 workers, reported a medical cost of \$5.11 per employee for 1936 as compared with a previously reported cost of \$6.30 per employee in 1932. The reporting companies bore all medical costs and maintained a minimum of a first aid room, an attendant—usually a graduate nurse, and doctors serving on call, or part to full time. The greater per capita cost in 1932 is partially explained by the fact that medical service, though reduced, was not curtailed as rapidly or as much as was employment during the depression period. Consequently, the medical costs were spread over comparatively fewer employees. Furthermore, the recent marked increase in number of workers in industry also accounts for the apparent reduction in per capita cost in 1936, when in reality the total medical cost would be considerably greater in 1936 than in 1932.

The gradual increase in annual per capita medical costs has not been an increasing burden on employers. On the contrary, this expenditure for medical service has effected far greater savings, by reducing labor turnover, by maintaining healthier, happier, and more efficient workers, by reducing accidents and occupational disease, and by reducing absenteeism in general. The per

TABLE II—PER CAPITA MEDICAL COSTS IN INDUSTRY

Year	Cost
1915 ¹	\$0.88
1917 ¹	2.21
1921 ²	4.43
1924 ²	5.14

500-999	83	81,349	6.97	4.33	11.30
1-499	39	13,456	8.76	4.76	13.52

Source—American College of Surgeons

capita medical costs which range from 88 cents in 1915 to \$5.11 in 1936 are shown in Table II.

Costs by size of plant In the study of the 299 companies previously mentioned, the College found that establishments having 1,000 or more employees showed a per capita cost for medical and compensation purposes of \$8.42 as compared with a cost of \$13.52 for the plants having less than 500 workers (Table III). Better organization of the medical and safety services in the larger plants accounts largely for their lower costs.

Distribution of medical costs. According to reports from 268 companies that spent \$4,111,296.56 in 1936 for medical service for their employees, 63 per cent of this amount was paid to doctors and nurses, 15 per cent to hospitals, 13 per cent for administration, and 9 per cent for supplies. These employers maintain a minimum of a first aid room and a nurse, and doctors on call or part to full time, but they do not provide home medical care for employees or their families. The 13 per cent spent for administrative purposes is significant in that it reveals that employers are now, more than ever, willing to spend money for a "follow through" and support for their medical service and thereby obtain greater benefit from their program of health maintenance. It is urged that industrial physicians and surgeons recognize this trend and participate more actively in the administrative phase in order that the future voyage of industrial medicine and surgery may be better charted.

with the various departmental heads in the prevention of industrial injuries and illnesses.

The prevention of infection is still a problem in industry. In the state of New York 15 per cent of all compensated cases in 1932 were infected cases. Approximately 10 per cent of all occupational injuries compensated in 1935 were cases of infected wounds according to the reports of industrial commissions of 4 states. At this rate it has been estimated that compensation for infected injuries would total at least \$11,000,000 per year in the United States. Much of this cost might be saved if every injured workman were required to report promptly for proper first aid or medical treatment. The provision of the necessary care for industrial injuries is of course required of the employer by the workmen's compensation laws. Experience has shown that the best surgical and hospital service is the cheapest.

4 *First aid and advice for employees suffering from non industrial injuries and illnesses while on duty.* Reasonable first aid and advice may be given to employees who are suffering from non industrial injuries and illnesses while on duty. For further professional care however, such employees should be referred to their own private or family physicians. If the worker does not have a private physician he should be aided in selecting a competent one.

5 *Medical supervision of plant sanitation and of all industrial health measures.* The direction and supervision of the health program or medical service should be a duty of the medical director. Probably no phase of the average industrial medical service has been so badly abused or neglected as that of supervision of the medical service. Surveys by the College have revealed that while some of the larger industrial organizations have had proper medical supervision, most medical services are supervised by others than physicians or surgeons. If such logic is sound, we should then expect to find plumbers in charge of sales promotion work and advertising heads transferred to the foundry.

Fortunately, there have been some constructive changes, though gradual, in this respect and in the past year some of the largest industrial organizations in this country have employed competent physicians or surgeons to correlate and supervise their medical services. Adequate medical supervision will assure adequate medical service. The industrial physician of the future, however, must add administrative duties to his purely professional services.

Regulations for the first aid and medical service at the plant should be formulated and signed

by the physician in charge for the guidance of assistants and first aid attendants. Periodic visits should be made to the plant dispensary to see that such standing orders are enforced. Periodic inspection trips through the plant should also be made by the physician in order to ascertain working conditions, job requirements and the presence or absence of health hazards.

RECENT TRENDS AND EXPERIENCES

Injury rates. According to the report of the National Safety Council the injury frequency rate for all industries in 1936 was about the same as it was in 1935 but the severity rate increased 5 per cent in that period. From 1926 to 1936, however, there has been a decline of 61 per cent in injury frequency rate and 40 per cent in severity rate for all industries. The public utilities have made the greatest reduction in injury rates during this 10-year period. We should bear in mind that good medical service has been and can be responsible for approximately one third of the reduction in injury rates.

Occupational disease incidence. Approximately 1 per cent of the compensated cases in New York State during a 3 year period, 1933 to 1935 were awards for occupational disease. Other authorities are of the opinion that occupational disease accounts for approximately 2 per cent of the total disabilities from industrial causes. From 1935 to 1936 there was a 43 per cent increase in occupational diseases reported in New York State, whereas the total number of industrial injuries reported increased only 23 per cent in the same period. The length of disability caused by occupational diseases has averaged about the same as that caused by industrial injury.

Absenteeism. In a limited study made by the American College of Surgeons 116 companies in various parts of the United States employing 352,591 workers reported a loss of 208,648 days in 1936 on account of industrial injuries—a loss of approximately one half day per person. Included in these reports to the College, from companies in which quite accurate data are kept on absenteeism, were findings which showed that the average worker loses 15 times as much time from non industrial injuries and illnesses as he does from industrial injuries. Consequently if 50,000,000 workers in the United States lose 400,000,000 days annually on account of injury and illness this would represent a loss to the

¹ Allowance must be made for variation in the method of record keeping among various industrial organizations. If we were the statistical data submitted to the College are sufficiently accurate to show trends in either absenteeism or costs.

COMPLETE AVULSION OF THE SCALP AND LOSS OF THE RIGHT EAR

Reconstruction by Pedunculated Tube Grafts and Costal Cartilage

JAMES A. CAHILL, JR., M.D., F.A.C.S., and PHILIP A. CAULFIELD, M.D., Washington,
District of Columbia

WHILE scalping is commonly associated in the lay mind with the aborigines of our western plains, there is scattered anthropological and historical evidence to the effect that it was practiced regularly as an act of war even in the days of Herodotus, who himself described the custom as observed among the Scythians. Occasional explorers and travelers in Asia, Europe, and Africa have returned with fragmentary accounts of scalptaking by savage tribes as well as by certain barbaric races. Naturally, instances of scalping by uncivilized peoples were seldom or never reported in medical literature, hence our knowledge of the prevalence of the practice and the frequency of its employment prior to the mid-nineteenth century is based mainly upon the random references already cited.

However, coincidentally with the wider utilization of machinery in manufacturing, cases of accidental avulsion of the scalp have gradually become more numerous, until the term as at present employed is virtually synonymous with industrial scalping.

In his authoritative monograph on the subject of accidents by scalping published in 1911, John Staige Davis recorded a total of 92 cases of complete avulsion of the scalp from all causes, culled from an exhaustive study of the medical literature of the entire world up to that time, 81 of them by machinery. The first of these occurred in England in 1838 and was reported one year later by Downs. A girl of 17 caught her hair in a rapidly revolving horizontal shaft and was completely scalped, the line of tearing involving both eyebrows. Despite expectant treatment consisting in part of simple dressings and partly of dressings soaked in a weak zinc solution, healing was slow with smooth, flabby granulations, and a portion of the denuded parietal bone was exfoliated. The patient suffered from continued irritation and

discharge accompanied by cough and fever. Erysipelas finally developed, and death followed 8 months after the accident.

Four additional cases of complete industrial scalping were reported during the period of 30 years succeeding the failure recorded by Downs, and antedating the application of skin grafts for the repair of the resultant defect. In these cases, all in young women, healing was effected by cicatrization in 2 patients, while a third patient declined further medical care after 8 months of unsuccessful from simple bandaging, and died half a year later. The fourth patient succumbed to pneumonia and pachymeningitis on the 24th day following reattachment by silk suture of the avulsed scalp.

The art of rhinoplasty, the forerunner of our modern system of plastic surgery, was known to the ancients, as a reference to the procedure in the *Ebers Papyrus* (about 1500 B.C.) attests. However, the operation appears to have attained to its highest degree of perfection in antiquity among the Brahmans of India, who are said to have utilized for the purpose pedunculated flaps from the cheek and forehead and even to have attempted plastic surgery of the ears as early as the second century of the pre-Christian era. In his erudite study of the history of skin grafting, Ehrenfried relates that there were among the Brahmans certain individuals of low caste who specialized in the repair of the mutilated features of malefactors whose ears and noses had been amputated as a penalty for their crimes. Another procedure of these pioneers in plastic surgery consisted in castigating the skin of the buttock until it had become markedly congested, excising a portion of the skin together with its subcutaneous fat, transplanting it by uniting it to the previously freshened edges of the defect, and finally suturing in position.

After a long period of disuse, the practice of rhinoplasty was in the 16th century resumed in Italy, whence it was believed to have been imported by the Arabs. In 1597, Gaspar Tagliacozzi of Bologna, a skilled otorhinologist of his

Presented in the Symposium on Industrial Medicine and Traumatic Surgery, before the Clinical Congress of the American College of Surgeons, Chicago, October 25-29, 1937.

SURVEYS BY THE COLLEGE

During the past year the medical services of 1,657 industrial establishments representing approximately 5,500,000 employees have been under survey by the American College of Surgeons. Of this number 843, or 50 per cent have been provisionally or fully approved as of October 1, 1937. To those industrial establishments in which the medical service is fully approved and is of such a nature as to give reasonable assurance of continued compliance with the minimum standard, a certificate of approval is granted.

The number of new establishments added to the list for survey during the past year has not been as large as in former years. More attention has been directed to the organizations previously

surveyed in which there was not only the opportunity but an urgent need for constructive work.

The co-operation extended to the College by the various industrial organizations in this movement to make efficient medical service readily available in industry through effective organization has been most active and encouraging. Many constructive health measures for employees have been recently instituted by employers in order to care better for the human machine in industry.

No doubt this progress is a result of the growing realization on the part of industrial managements that the human element is the most important factor in the structure, operation and product of any industrial organization.

of Ollier's effort to improve upon Reverdin's operation, and the fact that the method originally devised by him was appropriated with only slight modification by Thiersch, clearly entitle the name of Ollier to precedence in the hyphenated eponym Ollier-Thiersch adopted by a few medical lexicographers.

Eventual dissatisfaction with Thiersch grafts led in due course to the revival of the free flap according to the second Indian method, first by Wolfe of Glasgow in 1875 and later by Krause of Altona, who is credited with the establishment of the procedure in surgical practice in 1893 under the title of the Wolfe-Krause method. This was in turn succeeded by the renaissance during the latter part of the 19th century, primarily through Maas, of the method of the pedunculated flap obtained by one of the procedures already described, namely, French, Indian, and Italian (Tagliacotian). A modification of the latter method was utilized in our case of complete avulsion of the scalp.

Grafts for the treatment of complete scalping were employed originally in 1869 by Netolitzki, who transplanted small, elliptical shaped pieces of skin of whole thickness from the back of the hand of a female patient of 24 years. A colleague, Philipp, later attempted to transplant skin from

dogs and rabbits (zoodermic grafts) to the same patient. The lesion remained unhealed after 2½ years of treatment.

The use of Reverdin autodermic grafts for the treatment of complete scalping was essayed first in 1871, in the United States, by Bartlett, who applied them quite successfully to a woman aged 19.

This case, reported in 1872, only 3 years after Reverdin's original description of his method, apparently is the earliest recorded instance of total avulsion of the scalp treated by that method.

In 1889 Socin was the first to utilize Thiersch grafts (in conjunction with Reverdin grafts) in the treatment of complete scalping in a girl of 15. Healing ensued in his case after 10½ months.

The 96 cases of complete industrial scalping reported to date involved 95 females and 1 male (a Chinaman, whose queue was caught in machinery), the youngest aged 8, the eldest 63 years. Of these cases, 23 occurred in the United States. In 58 cases the line of tearing included one or both eyebrows, in 21 the line of tearing passed above the eyebrows, while in 17 the line of tearing was not clearly specified. The left ear was involved in 13 and the right ear in 12 cases, and in 1 case in which the ear is said to have been included the side is not stated.

time, introduced a modification of the usual operation, which had during the preceding century been monopolized by the Brancas a family of plastic surgeons of Sicily. In a formal treatise on the subject Tagliacozzi described what has since come to be known as the Italian (or Tagliacotian) method whereby the flap is obtained from a distant part, generally the arm and shifted to its new position by single or multiple transfer. This was in contrast to the earlier Indian method until then in vogue, in which the flap was obtained from the immediate vicinity of the defect and transferred to its new position by rotation on its pedicle. Tagliacozzi's method ultimately fell into disrepute and the practice of face repairing was subsequently condemned by ecclesiastic and medical authorities alike.

A third method of obtaining pedunculated flaps the so called French method originally devised by Celsus and developed especially by the French, hence its title, consists of the sliding of flaps from adjacent tissue with little or no torsion of the pedicle.

In 1869, Jacques Louis Reverdin proved that small particles of epidermis placed upon a granulating surface promoted healing and thus established his method of 'epidermic grafting' although as Reverdin himself pointed out, the designation was not entirely accurate since the

transplanted bit actually consisted of the whole epidermis and a very small part of the dermis. The method was at once adopted in several countries of Europe and even in America, and all went well with it at first. However, it was soon discovered that while Reverdin grafts expedited natural cicatrization they caused contractures especially in the region of joints.

In an endeavor to overcome these disadvantages, in 1872 Louis Ollier evolved his procedure of dermo epidermic grafting with films of epidermis containing a portion of the dermis much larger than those employed by Reverdin, pared off in strips and applied to the surface of a wound after shaving down the granulations. Unlike Reverdin Ollier did not seek to produce multiple centers of epidermization but to substitute for the integument of an ordinary cicatrix a surface possessing the essential elements of normal skin.

Ollier's method likewise enjoyed only brief favor and served chiefly as a basis for subsequent experimentation by Karl Thiersch who in 1874 reported tentative results obtained with his adaptation of Ollier's technique, the modified procedure involving merely the use of still larger pieces of skin of whole thickness from which the adipose tissue had been carefully removed. However it was not until 12 years later (in 1886) that Thiersch finally announced his perfected method which has since been known almost universally as Thiersch grafting. None the less, the priority

Fig 12

to the center, and held by catgut sutures. The entire area of operation was flushed with a 0.5 per cent chlorine solution, a large sheet of oil silk soaked in liquid paraffin was spread over it, and pressure was applied by a capeline bandage. By the seventh day the flaps were firmly adherent to the pericranium. No hairbearing flaps were destroyed, the hair grew well after 4 months, and the areas of granulation then appeared smooth and flush with the adjacent scalp. Mild doses of ultraviolet rays on alternate days for a brief period completed the cure.

Recorded instances of attempts to reconstruct a missing ear are exceedingly rare, perhaps because of the risk of infection of cartilage, with shrinkage consequent upon chondritis or perichondritis, the problematical cosmetic result, and the possibility of postoperative atresia of the canal. However, the revival during the world war of the use of the pedunculated flap, this time in the form known as the pedicled tube graft, rendered readily practicable the safe and satisfactory restoration of a traumatic auricular defect, primarily through the possibility by means of

this type of graft of transferring portions of cartilage which serve to impart stability to the softer structures involved in the molding of the ear. Lockwood, a pioneer in the introduction of the pedicled tube graft for plastic reconstruction of the ear, recently reported 2 highly successful cases of its employment in conjunction with reinforcement by costal cartilage for the repair of partial avulsion of the auricle.

In the case which we are about to report, following the failure of pinch grafts to repair the defect resulting from scalping, pedicled tube grafts were

Fig 7 left The new tube taken from the left side This is a large pedicled graft and has now been attached at the base of the skull posteriorly near the occiput This tube is to form the large covering for the avulsed area

Fig 8 Lateral view looking from the right showing loss of the right ear The smaller pedicled graft is now in place at the right ear the large tube is attached posteriorly

The entire avulsed scalp was replaced in 1 piece in 21 cases, in all but 1 of which there was total failure, complete healing occurring in the single exception after 98 days In this extraordinary case, reported by Malherbe in 1898 the scalp was cleansed with sublimate solution (1 to 1000), and reattached with 40 sutures counter openings being made in the vertex of the skull and 8 drains placed in the scalp and in the skin of the forehead and neck According to an account by Lejars quoted by Davis the scalp died but was converted into a parchmentlike covering or dressing of skin adherent to the cranium under which healing occurred without complications

Cases of complete industrial scalping recorded in which patients were treated by the Reverdin method numbered 7 all with apparently successful results Patients treated by the combined Reverdin and Ollier Thiersch methods totaled 10 with 7 successes and 3 failures Cases in which treatment was reported as by the Thiersch (that is to say Ollier Thiersch) method alone aggregated 25 with eventual healing in every one The type of procedure and the ultimate result of treatment are not specifically stated in the histories of the other cases of skin grafting It is interesting to note that small ulcerations which proved more or less resistant to treatment appeared on practically all grafted areas

Gould is believed to have been the first to employ a pedunculated flap (in his case from the back of the patient's neck) in 1908, to hasten healing of an area previously treated unsuccessfully with several Thiersch graftings Other expedients essayed in an effort to promote repair of the defect in a girl of 16 included implantation of the lining of a dermoid cyst and application of skin excised from a large ventral hernia All 3 attempts failed to produce an immediate effect in this case However the entire wound was almost completely healed about 2 years after the accident

In a case recently contributed by Mitchell an entirely new method of restoration originally devised by him comprised a series of incisions clear down to the pericranium, 3 at the lateral and 2 on the anterior and posterior aspects the resulting flaps being about $\frac{3}{4}$ inch wide with sufficient attachment at each end to allow of an adequate blood supply each succeeding whole thickness flap being undercut and levered toward the center without regard to hemorrhage The upper lateral flaps were first sutured together with strong catgut and the next lateral flaps were then sutured to the first leaving a gap of half an inch and the third lateral flaps next sutured to the second, leaving another gap of half an inch Anterior and posterior flaps were undercut, levered

a small area on the left, which later granulated satisfactorily. The pedicled graft was placed in position on the right side of the head near the ear.

A third plastic operation was performed under avertin and gas anesthesia on December 19, 1935. A second pedunculated tube was made on the left side of the back. This was much larger and contained considerably more skin. The purpose of this flap was to cover the entire avulsed area of the scalp. This tube was permitted to grow and establish itself. Following this operation the patient lapsed into shock, and a blood transfusion and stimulation were required.

Two months later the condition of the tube graft on the left side appeared satisfactory and the general state of the patient was markedly improved. At this time the pedunculated tube graft from the left side of the back was attached to the left side of the scalped area in the occipital region. The graft held firmly without any evidence of supuration.

After 2 more months the graft was entirely detached from the back, the pedicle was turned, and it was then attached to the forehead, presenting a large area of full thickness skin attached anteriorly above the eye and posteriorly at the occiput. This tube graft was quite heavy and adhesive plaster was necessary to support it so that it might not detach itself from the newly grafted area. Later this wide tube was opened and spread over the entire scalped area and sutured in position. The patient's condition was not too good, and only brief procedures were permissible, so that the time required for the various steps of this grafting procedure was naturally longer than usual. Several plastic operations were necessary to smooth the flap over the scalp and give it the proper conformity and contour.

Later the tube which had been placed for the right ear was molded to produce an ear with some shape, as shown by measurements made on February 14, 1937.

Left ear	Right ear
6 cm long	6 cm long
2 5 cm wide	3 5 cm wide
6 5 cm in circumference	9 5 cm in circumference
Distance from sinciput— 15 cm	Distance from sinciput— 16 cm

The final plastic operative procedure was the transplantation of a large piece of cartilage from the seventh rib on the left side. This cartilage was placed in the tube graft which had been previously fitted at the side of the ear. The tube was opened and the cartilage inserted therein so as to give the ear its erect appearance.

The patient left the hospital following this final procedure. The last plastic operation was performed approximately 19 months after the original injury.

It is our opinion that another pedunculated tube taken from the axilla and transplanted on the right side of the forehead would make even a more satisfactory and presentable appearance. However, the patient who has been most co-operative, seems entirely satisfied. The scalp is well covered and protected and a transformation which has been secured gives this patient a cosmetic result that is most desirable. She certainly has no reason for any em-

barrassment and presents only slight deformity, which is negligible after the artificial hairdress is in place.

SUMMARY

1 Avulsion of the scalp is a rarity. However, every surgeon, general or plastic, should be familiar with the possibilities of grafting for the repair of such an injury, particularly in industrial surgery.

2 A review of the literature and our own practical experience prove that the Ollier-Thiersch and Reverdin grafts are not satisfactory in the reconstruction of large areas of avulsed scalp.

3 It is necessary to protect the cranium and pericranium adequately by a definite full thickness skin flap, in order to have a transformation or artificial hairdress approximate it satisfactorily.

4 Pedicled tube grafts obtained either from the axilla or back are the most desirable for the purpose of the full thickness skin flap which is to be utilized in replacing the scalp.

fashioned from pedunculated flaps dissected from both sides of the back and transferred one to the scalped area the other to the site of the avulsed ear where the absent member was reconstructed with the aid of transplanted costal cartilage. The successive stages of the entire procedure are admirably illustrated in the accompanying photographs

CASE REPORT

CASE 1: Mrs I K, aged 25 years, a garment maker while at work on the afternoon of September 3, 1935 stooped to pick up an object which had fallen under her machine. In doing so her hair was caught in the flywheel of the machine and the entire scalp together with the right ear was torn off.

The patient was admitted to Providence Hospital in a state of profound shock. Examination revealed complete

Fig 13 The attachment of the small tube at the site of the external auditory canal. The ear is now beginning to assume some shape and conformity. The scalped area has been covered.

Fig 14 A profile or lateral view showing scalp completely covered and ear in position. The cartilage has been transplanted to give it conformity and to prevent sagging of the tube.

Fig 15 Shows patient following recovery with artificial hairdress or transformation in place. Note the absolute lack of disfigurement. There is no tightness to the scalp and no discomfort.

traumatic avulsion of the right side of the scalp down to the pericranium and of the right ear extending downward on the forehead and backward to the occipital region above the neck. There was also an adjacent area on the left side of the scalp completely torn off. The only remaining portion of the scalp was a small area in the left temporal and parietal regions.

Treatment for shock was immediately instituted. Large simple dressings were placed over the denuded areas, and antitetanic serum was given. The dressings were ordered continued daily until the patient became healthy and free from the possibility of infection.

It was not until 3 weeks later on September 24, 1935 that pinch grafts were applied to the scalped area under avertin and gas anesthesia. A pedunculated tube graft was also dissected from the back as the first stage of the plastic operation for reconstruction of the right ear.

On October 7, 1935 the patient's condition appeared quite satisfactory. The pedicled graft was growing nicely. Although some of the pinch grafts had taken the majority of them had sloughed away. It therefore appeared necessary that some other form of grafting be employed to cover the pericranium.

Accordingly on November 7, 1935 under avertin and gas anesthesia a plastic sliding graft was applied to the scalped area. This sliding graft was made by using the small area on the left side of the head which had not been avulsed and undermining and sliding it over to the center or middle portion of the head. This then left two areas of denuded skin, namely the avulsed area on the right and

Fig 1. a, left, Malunited Pott's fracture b, Good weight bearing alinement after supramalleolar osteotomy of tibia, note engagement of fragments of fibula necessary to maintenance of reduction following osteotomy

In all open reductions there should be as little detachment of the soft structures as possible, as the circulation to the bone is largely derived from this source, there will be arrest or delay in the delicate physiological process of repair if there is excessive stripping of the periosteum from the circumference of the bone

It is practically certain that a much better mechanical procedure can be carried out by wide exposure of bone, but often the purpose of

Fig 2 Fusion combined with osteotomy for malunited Pott's fracture.

the procedure is defeated by retarding the process of repair.

Delayed union in fractures is becoming much more frequent, and is a very definite contributing factor to malunion. The increase in number of fractures in which repair is retarded is due to three factors: (1) a relative increase in the number of fractures in recent years; (2) more severe injuries to the soft structures than ever before, and (3) repeated attempts to reduce a fracture, excessive skeletal traction, or destructive or excessively traumatic surgery which impairs the physiological process of repair. When union is delayed, there is

Fig 3 a, left, Old depressed fracture of internal condyle of tibia with varus deformity of knee b, right, Good correction following osteotomy and insertion of graft into osteotomy site to maintain position

Fig 4. Lateral and anteroposterior roentgenograms of fracture of the posterior portion of the external condyle of the femur with valgus deformity of the knee

MALUNITED FRACTURES

WILLIS C CAMPBELL, M D, F A C S, Memphis, Tennessee

MALUNITED fractures are of such frequent occurrence as to be of prime importance, and yet there has been very meager consideration of the subject by the medical profession. This discussion is based upon an analysis of approximately 700 malunited fractures from the records of the staff of the clinic with which I am associated.

Fractures which were observed in malposition before union had occurred, i.e., delayed or non union, are not included, otherwise there would probably be 2,000 in which anatomical alignment of the fragments was abnormal. A malunited fracture or a fracture with vicious union is one in which there is clinical union in an abnormal relation, malposition or deformity.

Although motion may not be clinically demonstrated at the fracture site, consolidation is frequently not complete, the degree of union in a malunited fracture may vary from early callous, to complete solid osseous union. Function may be seriously impaired in various ways: there may be blocking of a neighboring joint by the projection of overlapping fragments, angulation and rotation of the fragments may interfere with proper balance or overriding of the fragments may induce material shortening.

The causes of malunion may be enumerated as follows: 1. failure to properly reduce the fresh fracture; 2. failure to maintain reduction until there is sufficient consolidation.

The first requires no explanation and is the more frequent, but a high percentage is due to the latter. Failure to maintain reduction is due to several causes which may be enumerated as follows: (a) insufficient immobilization during the process of repair; (b) inefficient routine observation; (c) insufficient protection after union is apparently solid; (d) disregard of the physiological principles involved in the healing of a fracture.

Fixation may be inadequate from insufficient dimension of the splints or plaster casts: for example, in fractures of both bones of the forearm a splint or cast that extends from the heads of the metacarpal bones to, but not above, the elbow is obviously insufficient. Frequently a cast is either

too loosely applied or becomes so after swelling has subsided, thus permitting displacement after reduction has been accomplished.

The failure to carry out efficient observation and after treatment is probably the cause of a large percentage of malunited fractures. When ever there has been a complete fracture with displacement of the fragments, roentgenograms should be routinely made to confirm proper position 1 week after reduction or before if symptoms suggest possible displacement. Before consolidation is complete the splint or cast should be removed and the member actually inspected and roentgenograms repeated, then, if the anatomical alignment is not correct, adjustment can easily be made. A roentgenogram should also be made after union is clinically solid, though this may not determine the degree of union present in adults. In fact, in adults union can rarely be determined by the roentgenogram alone until the lapse of several months. Malunion, especially angulation frequently occurs after union is clinically solid; this is particularly true of fractures of the shaft of the femur, middle and lower third of the leg and both bones of the forearm. Angulation can be prevented by maintaining position and alignment with appropriate apparatus until solid osseous union can be undoubtedly demonstrated both clinically and by roentgenograms.

The removal of a portion of a splint and the relatively early application of physiotherapy as a routine after treatment is the cause of many malunited fractures, whether this is done under the direct observation of the surgeon or by the surgeon himself. Regardless of how skillful the surgeon may be, internal displacement, especially in the region of a joint, can and does occur without apparent early external change and as is well known even the slightest change in position or angulation of a fracture near a joint may cause gross deformity and disability. In Pott's and Colles fractures such measures are frequently advocated.

There are measures to stimulate circulation and prevent excessive atrophy which are quite sufficient without disturbing fixation such as active use of the fingers and exercises to the shoulder and elbow in Colles fractures, and early weight bearing with absolute fixation in Pott's fractures.

Fig 1 a, left, Malunited Pott's fracture b, Good weight bearing alignment after supramalleolar osteotomy of tibia, note engagement of fragments of fibula necessary to maintenance of reduction following osteotomy.

In all open reductions there should be as little detachment of the soft structures as possible, as the circulation to the bone is largely derived from this source, there will be arrest or delay in the delicate physiological process of repair if there is excessive stripping of the periosteum from the circumference of the bone.

It is practically certain that a much better mechanical procedure can be carried out by wide exposure of bone, but often the purpose of

Fig 2. Fusion combined with osteotomy for malunited Pott's fracture.

the procedure is defeated by retarding the process of repair.

Delayed union in fractures is becoming much more frequent, and is a very definite contributing factor to malunion. The increase in number of fractures in which repair is retarded is due to three factors: (1) a relative increase in the number of fractures in recent years; (2) more severe injuries to the soft structures than ever before; and (3) repeated attempts to reduce a fracture, excessive skeletal traction, or destructive or excessively traumatic surgery which impairs the physiological process of repair. When union is delayed, there is

TREATMENT

The indications for treatment and the type of treatment selected depend upon the individual case. The degree of deformity, location of the fracture, age, temperament and general condition

Fig. 6 Same patient. Satisfactory alignment and position with solid union following osteotomy and reduction

Fig. 7 Malunited fracture of shaft of femur with marked overlapping of fragments

of the patient must be duly considered. Slight deformity, with excellent function and without pain and disability is not sufficient indication for operative measures regardless of the earnest desire of the patient. Any individual who is willing to undergo a major operation for the correction of a slight irregularity will usually not be satisfied with the cosmetic result, or will develop symptoms elsewhere of equal gravity. The age of the individual is of material importance. In children correction of gross deformity may often be accomplished by growth, consequently unless quite severe a course of watchful waiting is often rewarded by a perfect result. Otherwise operative correction can be carried out with success at a later time.

When malunion and deformity are associated with an epiphyseal injury which has caused abnormal growth successive correction by operative measures may be required before full growth is attained to prevent distortion of soft structures.

In older individuals above the age of 40 years if there is gross deformity with functional impairment and disability correction is indicated as in younger people but the type of operation may vary to some extent. For instance, an extensive and prolonged procedure to correct alignment and decrease shortening of a malunited fracture would be considered in a young individual. In an older patient, osteotomy alone with good align-

Fig 8 Malunited fracture of the shaft of the femur which is complicated by marked overlapping of the fragments

Fig 9 Same patient Excellent position following open reduction supplemented by onlay bone graft to insure union and maintenance of position

ment would probably suffice, with less risk and possibly a better functional result

The prophylactic treatment of malunion or the efficient treatment of fresh fractures will materially reduce the high percentage of malpositions, but until this is accomplished malunion will be of frequent occurrence

Correction of malunion is accomplished by operative measures, the nature of which may be enumerated as follows (1) manual correction; (2) osteotomy with (a) skeletal traction or alone, (b) open reduction, (c) internal fixation, (d) bone graft, (3) tenoplasties, fasciotomies, etc., (4) plastic reconstruction, (5) elongation with wedging by autogenous grafts to restore normal plane to joint surfaces, (6) fusion of adjacent joints, (7) operative measures for correction of associated deformities

The object of these procedures is to restore not only function and anatomical alignment but as nearly normal external contour as possible, a good cosmetic result is greatly appreciated, particularly in women

Of the 700 malunited fractures, operative measures were employed in 303 patients, of the remainder, either conservative measures were employed or the patient declined operation, and are

mentioned only to demonstrate the frequency of occurrence

The distribution of the operative cases may be tabulated as follows:

Part	Cases	Part	Cases	Part	Cases
Phalanx	1	Tarsus	7	Os calcis	14
Ankle	47	Tibial shaft	20	Tibial condyles	8
Femoral condyles	8	Femoral shaft	46	Femur upper third	5
Clavicle	5	Shaft of humerus	1	Lower third of humerus	51
Upper humerus	1	Both bones of forearm	6	Shaft of radius	15
Monteggia fracture	7	Colles'	48	Phalanx	2
Ulna, distal third	3	Metacarpals	5		
Carpals	1				

The procedures employed can best be demonstrated by discussing malunion in certain locations of most frequent occurrence. Obviously only a very general consideration of the subject can be made, as malunion in one location could form the basis for a lengthy discussion, as malunited Pott's or Colles' fracture.

While the majority of malunited fractures must be treated by open operative procedures, a small percentage, particularly of the shafts of the long

Fig 10 Lateral and anteroposterior roentgenograms of malunited supracondylar fracture of the lower part of the humerus

Fig 11 Same patient Satisfactory position after osteotomy position maintained by boiled homogeneous bone peg

bones, are amenable to manual procedures. In adults, if consolidation is not complete or in children angulation and rotation deformities particularly, may be corrected without surgery. Even with overlapping of the bones, union may be broken up manually followed by skeletal traction to decrease the amount of shortening with an ultimate good end result. Manual methods of correcting malunion must be attended with skill and care or fractures may be produced which complicate the pre existing deformity.

Malunited fractures about the ankle are of frequent occurrence. Operative measures were employed in 47 cases. In young individuals and in those in which there is no secondary traumatic or static arthritis, supramalleolar osteotomy of the tibia has been employed. In recent years in malunited Pott's fracture with a valgus deformity I have found that better alinement in the ankle could be secured if the osteotomy is through the tibia just above the internal malleolus and through the fibula at the point of fracture which is usually about 3 inches above the tip of the external malleolus. An oblique osteotomy is made so as to elongate the fibula then the fragments are notched and engaged or rarely internal fixation by the aid of a rustless steel wire may be employed. This reduction and engagement of the fragments of the fibula are of great importance in all fractures of the leg otherwise there is difficulty in maintaining perfect anatomical alinement. This factor particularly prevents rotation with a change in the static relations of the articulations of the ankle and foot.

In malunited fractures of the ankle in which there is inversion, elongation of the tibia is indi-

cated, and can be accomplished to a satisfactory degree by osteotomy and the removal of a graft from the anterior surface of the tibia through a separate incision. This graft is inserted into the line of the osteotomy so as to bring about the desired degree of correction. Usually from one fourth to one half inch increase in length can be accomplished which is all that is ever required. This not only restores the normal transverse plane of the lower extremity of the tibia and the ankle joint, but maintains this position until union is solid.

In malunion associated with subluxation open reduction may be employed in those observed early, but it requires such an extensive intra-articular dissection that the prognosis is doubtful. In those encountered after the lapse of over months, the feasibility of securing a movable joint without pain is questionable. In those in which the malunion has existed for a long period of time with secondary changes manifested in the joint, and in elderly individuals, fusion of the ankle with or without correction of alinement by osteotomy has been employed with very gratifying results and relief of disability regardless of ankylosis of the ankle joint. Undoubtedly fusion of the ankle should be more frequently employed in selected cases, for by this measure a serious disability may often be practically relieved.

In fractures involving the condyles of the tibia there may be depression with or without separation of the condyles. The knee may deviate into varus or valgus depending on whether the medial or lateral condyle is involved. There is usually a satisfactory or normal range of motion but with lateral instability due to apparent elongation of

Fig 12 Malunited comminuted fracture of lower end of humerus with solid bony ankylosis of elbow

Fig 13 Same patient after correction with arthroplasty

the ligaments, the relaxation being due entirely to the increased space between the articulations caused by depression of one of the condyles. Correction is usually accomplished by a complete transverse osteotomy through the entire tibia about 2 inches below the articular surface, after which a graft of about 0.75 to 0.5 inch in width and 2 inches in length is taken from the same or opposite tibia and inserted into the line of fracture so as to raise the depressed side. Unless there is such great separation of the condyles that the articulation is not tenable, no attempt should be made to enter the knee joint or to approximate the separated condyles. When approximation of separated malunited fractures of condyles is necessary, apposition can be maintained only after osteotomy by internal fixation, as with rustless wire nails or bolts as employed in fresh fractures. After the operation is completed, there will be no relaxation in the ligaments and the joint will be perfectly stable. The tibial plateau is restored to the normal plane and so maintained by the graft inserted at the point of osteotomy. Union is usually secured in 8 weeks, a brace should be employed to prevent lateral movement in the joint.

Malunited fractures of the condyles of the femur do not require osteotomy with elongation by bone graft as frequently as the condyles of the tibia. But restoration of the plane of the femoral articular surface to as near normal as possible is required. This is usually accomplished by an osteotomy through the line of fracture or as near as possible, after which the displaced condyle is

brought down to the normal position and is transfixed by two long rustless steel nails. Great care must be exercised not to detach any more than necessary, the soft structures from the fragment to be repaired; otherwise more or less sequestration may occur, causing an irregular or incongruous joint.

In open operative measures for malunited fractures of the shaft of the femur, plastic procedures must be devised so as to permit as much elongation as possible after osteotomy. Those of short duration with an overlap of fragments or with angulation may be dissected loose and made transverse, after which reduction may be accomplished by angulation and by bringing the lower fragments in line with the upper until complete locking may be accomplished. Rarely, approximation with locking of fragments may be accomplished only by extending the hip and bringing the upper fragment down to the lower. Usually after reduction the tension is so great that firm fixation is secured; however a Kirschner wire is always inserted through the femur just above the level of the condyles and incorporated into the cast so that skeletal traction may be employed later if there should be a disengagement of the fragments with a recurrence of malposition. In those in which fixation is secured by bringing the lower fragment to approximate the upper, the extremity is immobilized in flexion of the hip and knee to about 150 degrees and abduction of the hip to 120 degrees. When approximation can be made only by bringing the upper fragment down to the lower, the limb is

Fig 14 Malunited Colles fracture note dorsal angulation of distal end of radius and radial shortening

Fig 15 Same patient Radial shortening and angulation corrected following osteotomy and insertion of two-dimensional wedge obtained from prominence of ulna

placed in a straight line with the slight abduction and the hip and knee are extended. Union is usually secured without decrease in length of more than one half inch or less.

In those fractures of long duration in which there is only about 1 inch shortening, a simple transverse osteotomy as in the correction of a varus deformity of the knees is usually sufficient great care being used to correct the tendency of the lower fragment to rotate inward. If there is shortening of over 2 inches, osteotomy by a more or less Z plastic or oblique severance may permit an increase in length. If only an osteotomy or chisel is employed irregular fractures in undesirable directions may occur consequently in order

to sever the bone accurately by any well planned osteotomy drill holes are made to outline the line of osteotomy, and then osteotomy is made by a chain saw or small chisel. If possible a motor saw should be used but this may require too much separation of soft structures from the bone.

After the oblique osteotomy if there is sufficient contracture to prevent an immediate increase in length, skeletal traction may be employed by means of the Kirschner wire or by the Roger Anderson appliance until as much increase in length as possible is secured after which external fixation by a cast is employed until union is solid.

Frequently in malunited fractures of the femur some means of internal fixation must be used to maintain the position of the fragments. This is most efficiently accomplished by means of the onlay bone graft, as it not only fixes the fragments but promotes osteogenesis so that union occurs in a much shorter space of time.

Malunited fractures of the clavicle, though of frequent occurrence rarely require correction. This has been necessary in only three instances. The procedure in the clavicle employs essentially the same principles as in the femur, but internal fixation by rustless steel wire is usually necessary. A long period of recumbency may be required if anterior and upward bowing is to be completely prevented unless a massive bone graft or some type of metal plate is used.

Fig 16 Same patient Perfect cosmetic result following bone plastic operation for malunited Colles fracture

Operative procedures for malunion of the upper extremity of the humerus are rarely required, as there is considerable compensatory motion in the shoulder, besides the shoulder itself is a rather loose joint and accommodates readily for considerable angulation and deformity. However, malunion may occur if dependence is placed upon an anterior posterior roentgenogram, a lateral view occasionally reveals gross displacement and angulation.

Malunion of the shaft of the humerus rarely if ever requires surgical correction, as good function, through compensatory motion of the shoulder and forearm, is compatible with considerable bowing and distortion.

Fractures of the lower end of the humerus involving the elbow joint are of frequent occurrence and often require operative correction. In this series there were 51 cases in which surgical treatment was required. In supracondylar and condylar fractures, a complete osteotomy in the line of fracture is required after which the fragments are restored to their normal position and so maintained with wire nails. The contour of the joint must be restored to as nearly normal as possible. At this location, aid is sought much earlier than in most locations, and as a majority in this location are in children, malunion is observed earlier. The results in children are excellent and much better than in adults. In adults after excessive comminution and incongruity of articular surfaces with excessive callus, an arthroplasty or reconstruction often gives by far the best results and should be more frequently employed.

In the forearm there were 31 fractures which required operative reduction. In malunited comminuted fractures of the head of the radius, excision below the bicipital tuberosity is indicated, but with varying results. In some instances function is restored to normal while in others there remains a more or less painful member with limitation of motion. This seems to depend on the fibrous and osseous reaction of the individual, regardless of care taken to remove completely periosteum and all spicules of bone. In fractures just below the head of the radius the slightest angulation may cause marked limitation in rotation of the forearm, consequently malunion in this location must be corrected by osteotomy and internal fixation. In this location even in children 10 years or older there may be a permanent limitation of motion.

Fracture of the upper third of the shaft of the ulna with dislocation of the head of the radius is a notorious combination—the so-called Monteggia fracture. Perfect reduction is difficult, but if not

secured, material impairment in function of the elbow may be expected. Malunion in this fracture occurs in a high percentage, and can be corrected by osteotomy of the upper third of the shaft of the ulna, after which the head of the radius is exposed and reduced, and so maintained by a transplanted strip of fascia lata passing about the neck of the radius and through the ulna. The osteotomy in the ulna is held in position by rustless steel wire, plate or bone graft and a plaster cast immobilizes the forearm and elbow.

Malunited fractures of the shaft of the ulna, except in combination with dislocation of the head of the radius, are infrequent. Malunion of the radius in the upper or lower third is much more frequent. In the upper third, forward bowing due to the pull of the biceps is the usual cause and must be prevented after osteotomy. In the lower third, there is also anterior bowing which must be prevented. In either location some type of efficient internal fixation may be advisable. Malunion of both bones of the forearm rarely requires operative measures, but, when necessary, simple osteotomies are usually sufficient with the greatest care to prevent backward bowing, especially in the ulna.

Malunion in fractures of the lower extremity of the forearm is of frequent occurrence, especially the malunited Colles' fractures. The patients present themselves to secure relief not only from the unsightly deformity but from persistent pain and disability. There were 48 of this type.

Three procedures may be employed to correct malunion of a Colles' fracture: (1) resection of a segment of the distal end of the ulna; (2) osteotomy of the radius through the fracture site; (3) bone plastic procedure. Resection of the ulna is a compensatory procedure with no attempt to correct the existing deformity. Osteotomy alone allows correction of the angulation present but is insufficient, in that radial shortening is not corrected and the distal end of the ulna continues to be prominent, resulting in a poor cosmetic result. The bone plastic procedure consists of a transverse osteotomy about 1 inch above the lower extremity of the radius, after which by a second incision the projecting portion of the lower extremity of the ulna is resected and transplanted between the fragments of the radius, thus elongating the radius to normal length and restoring the contour of the wrist joint to normal. This procedure was described before the orthopedic section of the American Medical Association at the Atlantic City meeting, and the description was published in the October 2, 1937, issue of the *Journal of the American Medical Association* to which

reference can be made for minute description of the technique

No attempt has been made to describe minutely the technique of correction of malunion of all bones, the principles described, however, may be employed in other locations. Physical therapy must be instituted but not until union is sufficiently solid to withstand the stress. No tried and fast rules can be given as each fracture is an individual problem unto itself, requiring experience and judgment.

All malunited fractures of the ankle require protection by apparatus from 1 to 7 months after removal of splints or casts. An arch support and brace with varus or valgus T straps are usually required.

In malunited fractures involving the articular surface of the knee physical therapy is instituted at the end of 4 weeks, after 8 weeks walking is permitted with the aid of a walking caliper. Thomas knee brace, which transfers the weight of the body to the ischial tuberosity and the perineum. Full unprotected weight is not permitted until union is absolutely solid and the osseous structure approaches normal, as demonstrated by the roentgenogram and by clinical examination. This may take as long as 4 to 6 months, but if weight is borne too early there will be either recurrence of the displacement or compression of the articular surface.

In all malunited fractures of the femur protection by means of a leather corset brace with Thomas ring support is required for several months after union is clinically solid. As soon as union is clinically solid physical therapy is employed to the knee but with caution.

In the upper extremity protective apparatus to insure maintenance of position until osseous union is complete is routinely employed but not as extensive or prolonged as in the lower extremity where too early weight bearing is such a preponderant cause of recurrence of malunion.

The end results in the treatment of malunited fractures cannot be estimated in percentages due to the varying complications present, but the re-

sults on the whole are excellent, with material decrease in disability, and in a small percentage complete restoration to normal.

Secondary compensating or associated changes in adjacent joints as distortions of the foot—equinus varus, valgus—and flexion of the knee are quite common and require separate surgical measures for correction, as tenotomies, fasciotomies, osteotomies, which are not pertinent to the subject.

There are several factors which should be emphasized.

1 The correction of a malunited fracture is an individual surgical equation which must be devised to meet the mechanical requirements of each case.

2 Protection by apparatus of malunited fractures after open reduction is usually required as after all open operations upon fractures, union is potentially delayed and there is danger of malposition.

3 Operative measures in malunited fractures that involve an articulation should avoid invasion of the joint when possible.

4 In malunited fractures about the ankle and the leg, the fracture of the tibia should not be disregarded. There should be accurate reduction of the tibia which is a very important factor in maintaining alignment, and preventing displacement of the foot and ankle. The same principle is of equal importance in fresh fractures to prevent malunion.

5 The employment of autogenous grafts for the purpose of elongation, the correction of deviation, and to restore the normal articular plane by inserting between fragments after transverse osteotomy is a valuable procedure that is successful in practically every instance if it is efficiently applied.

6 The large number of fractures encountered in which malposition is discovered before union has occurred in delayed union in non union and in actual malunion or vicious union is sufficient evidence that fractures are not efficiently treated and even more strenuous efforts should be made to rectify this condition.

PHYSICAL THERAPY IN RELATION TO INDUSTRIAL MEDICINE AND TRAUMATIC SURGERY

K. G. HANSSON, A B., M D, New York, New York

THE tremendous growth of human enterprise since the beginning of this century has been followed by new dangers to the health of man. It is a great responsibility that has been added to organized medicine, and it is our duty to use all our means to prevent industrial disability, as well as to treat the victims of our even more complicated modern communities. An important therapeutic measure in industrial medicine and traumatic surgery is physical therapy.

Physical means were the basis for treatment on the island of Cos in 400 B.C., where massage, exercises, water, and sun were used to restore the sick to health. In our days, during the World War all useful procedures in this line were concentrated in the base hospitals in order to get the disabled soldiers back to the front as soon as possible. Physical therapy received its "baptism under fire" so to speak. Many doctors were introduced to therapeutics of which they had little knowledge, but which they accepted indiscriminately. When the war was over the medical profession was confronted with modern industry enormously increased and producing problems similar to the war.

One of these problems was the care of the victims of modern industry and modern transportation. Physical therapy was employed extensively both by institutions and by private practitioners. Manufacturers flooded the market with all kinds of appliances which were forced on the medical profession by high powered salesmen. In 1927 the American Medical Association created a Council on Physical Therapy. This council is to physical therapy what the Council on Pharmacy is to the drug therapeutics. The Council on Physical Therapy is curbing commercialism and unwarranted claims for apparatus. It advocates basic training in undergraduate and graduate medical schools, as well as in the county and state medical societies.

The Council on Physical Therapy of the American Medical Association has defined physical

therapy as the application of heat and cold, the actinic rays, water, electricity, massage and therapeutic exercises. Physical therapy as you know it in traumatic surgery is only a part of physical therapy as a whole. Such treatments as underwater exercises for poliomyelitis, ultraviolet radiation in rickets, heliotherapy in extrapulmonary tuberculosis, hyperpyrexia in gonorrheal arthritis, corrective exercises and postural training, and hydrotherapy in the management of arthritis, are fairly well established.

What is the relation of physical therapy to industrial medicine and traumatic surgery, who should use it, and how much is rational therapeutics? I believe that there is little indication for specialists in physical therapy except in the larger hospitals and teaching institutions. Physical therapy should be a part of the surgeon's armamentarium. I agree fully with Dr. Mock who has said that 65 per cent of all industrial cases need physical therapy. Fifty per cent of these can be treated with application of heat, massage, and therapeutic exercises, the next 25 per cent require some apparatus, such as whirlpool baths, diathermy, and ultraviolet radiation which can all be done by the practitioner. Only the last 25 per cent require physical therapy methods that involve more experience and specialized knowledge, such as electrodiagnosis, ionization, etc.

The efficiency of heat and massage and therapeutic exercises in the management of the traumatic patient is such that it will answer our purpose in most cases. Much of the physiological action that we depend upon is through the circulation. Some years ago I worked out the following experiment: I injected 1/10 cubic centimeter normal saline subcutaneously, and found, if left alone, that it would be absorbed in 51 to 61 minutes. If massage was applied it would disappear in 6 to 9 minutes.

Table I shows the great value of massage; that it is far more efficient than the other modalities.

A few years ago I collected 100 consecutive traumatic cases in which the patient paid for his own treatments, and compared them with 100 consecutive compensation cases of similar diagnoses. I found that the latter cases received 20 per cent more treatments before discharge. There

From the Physical Therapy Department, New York Hospital and Hospital for Ruptured and Crippled

Presented in the Symposium on Industrial Medicine and Traumatic Surgery, before the Clinical Congress of the American College of Surgeons, Chicago, October 25-29, 1937

TABLE I—CIRCULATORY ACTION OF PHYSICAL MODALITIES

1/10 c cm normal saline injected subcutaneously is absorbed—	Minutes
Normally in	56 to 61
By massage in	6 to 9
By electric vibrator in	9 to 11
By ultraviolet radiation in	30 to 33
By static wave current in	30 to 33
By whirlpool in	30 to 33
By thermo-lamp—375 watts—60 cm in	35 to 38
By infrared—600 watts—60 cm in	40 to 42
By diathermy—cuffs—1000 m amp in	42 to 44
By galvanic current in	44 to 46
By faradic current in	46 to 47
By sinusoidal current in	47 to 49
By passive exercises—Zander in	50 to 55

were undoubtedly abuses of physical therapy. This was especially true between 1920 and 1930. Large industrial clinics were organized for profit rather than for cure. I know of one such clinic where one technician treated an average of 60 patients a day. Such treatments were of course inadequate to say the least. A reaction to such treatment in addition to the economic depression brought a more critical attitude toward the treatment of the industrial patient and especially the generous use of physical therapy in the convalescent stage. Physical therapy is on trial and I am willing to give my testimony. I am in charge of physical therapy in two large New York hospitals on a salary and therefore without financial interest as to whether a patient has one treatment or a hundred. I am concerned only with the complete restoration of the patient as early as possible. My judgment is therefore not exposed to temptations of prolonging treatments for financial gains.

In this paper I shall confine myself to the methods of physical therapy commonly used in traumatic surgery. My intentions are not to go into detail but I shall attempt to direct in a general way your appreciation of physical therapy.

Fractures. The modern treatment of fractures recognizes the break in continuity of the bone as well as the damage to the soft tissue. We must realize that we are dealing with a whole individual who has an extremity which has a fracture. Murray states that physical therapy in fractures minimizes chances of delayed union, prevents the organization of scar tissue in muscles, joint capsules and tendons, decreases the functional limitation that otherwise has to be dealt with after the bone has healed. If we review the physiological healing of a fracture based on experimental work on bone repair, we may divide this repair into 5 stages.

First stage. The immediate result of a fracture

is a hemorrhage, which is central, subperiosteal and muscular. This hemorrhage produces the clinical symptoms of pain, swelling and muscular spasm. These symptoms indicate nature's attempt at immobilization. After best possible reduction has been obtained, our efforts should be to maintain this.

Second stage. A few hours after the fracture, a productive inflammatory process begins, which through granulation tissue formed and the evaporation of fibrin and serum, changes into a hematoma. The clinical symptoms of pain, swelling and muscular spasm persist, they tell us to keep our hands off and to maintain immobilization.

Third stage. Forty eight to 72 hours after the reduction the hematoma surrounding the fragments is further organized by connective tissue osteoblasts appear, and some bone matrix is formed from the intracellular substance. Pain and muscle spasm have disappeared and swelling decreased.

Fourth stage. On the fourth or fifth day we have a soft callus consisting of osteoid tissue. The calcium salts (calcium phosphates and calcium carbonates) are deposited in the connective tissue stroma.

Fifth stage. After the first week the connective tissue is well organized, osteoid tissue appears and there is a general transition of the cells from connective tissue to osteoid tissue to bone. At this stage the patient often complains of stiffness in adjacent joints, the soft parts about the fracture are described as lifeless. Now we are dealing with a convalescent fracture in which the bony repair has gone into a soft callus, and there are no muscular spasm, swelling or pain which contraindicate restoration of function.

The physical therapy treatment should start in the third stage, i.e., the second or third day of healing whenever possible. The functional restoration should go hand in hand with the healing of the fracture. If this is followed there is no period of after treatment and when the fracture is healed the damaged soft tissue and the adjacent joints are normal in function. Muscular strength and coordination of muscles are best obtained by occupational therapy.

Where complications follow such as traumatic arthritis, contractures or bone atrophy, paraffin applications may be used or diathermy, short wave, or electrical stimulation of muscles.

I believe that this treatment should be directed and supervised by the surgeon responsible for the fracture. His duty is not only to bring about the union of the fracture but to return the patient to his pre accident functional activity.

The importance of active exercises cannot be emphasized too greatly. Let the patient take some of the responsibility, exercises with a purpose such as occupational therapy are superior to passive movements with expensive apparatus.

The infected hand. The infected hand is a very common and a very serious problem for the traumatic surgeon. Kanavel's work on this subject as to the pathology and surgery is a classic. However, after the hand has been properly incised, the restoration of function is often hampered by immobilizing dressings. The fingers are not moved for several weeks, and adhesions are laid down between the tendon and its sheath, the joints undergo arthritic changes, and the soft tissue atrophies, resulting in a very useless hand with a high percentage of disability. Physical therapy can be of real aid to the traumatic surgeon in these cases, in the form of whirlpool baths and active exercises. On the third day after the incisions have been made there is probably very little chance of any bleeding, and this is the time for submersion in the whirlpool for 15 to 30 minutes. The whirlpool bath is a basin into which water of 110 degrees is forced by 50 pounds pressure, forming a whirl. It has an osmotic effect on the soft tissue, a mechanical cleansing effect, and also produces slight molecular massage on the hand. The patient is encouraged to move wrist and fingers, which makes it similar to Willem's treatment which was popular during the war. The basins are cleansed with lysol after each treatment, and I have never seen any re-infection caused by this treatment. This procedure should be followed twice a day, and every 2 days a suberythema dose of ultraviolet to sterilize the skin and external wounds should be applied.

For localized infections anywhere on the body I have been much impressed by Cooley's compress. It consists of a rubber covered heating coil, which is controlled by a rheostat. It maintains a temperature of 140 to 160 degrees Fahrenheit. Between the coil and the skin we have a flannel compress, which is saturated with fluid. In the flannel compress we have a sleeve which runs to the center of the coil and holds a thermometer. Various kinds of fluids are used to keep the flannel compress moist. Boric acid is useful for eye infections, normal saline for preparation for a skin graft, half strength Dakin for osteomyelitis, and magnesium sulphate 5 to 10 per cent for localizing infections. Of course the patient is hospitalized, and compress is kept on both day and night. As in the treatment of fractures, the physical therapy should go hand in hand with the surgical treatment. If the functional treatment

is started only when the wounds are healed, it will often result in a "frozen hand." The treatment recommended for this condition is paraffin dips, strong electrical stimulation to the muscles, and active and passive exercises. The paraffin dipping is a simple procedure which can also be carried on by the patient at home. We use laboratory paraffin which melts at 150 degrees; then it is cooled to 130 degrees and the hand is immersed 12 times. The paraffin glove thus formed is kept on 15 minutes, and the hand is ready for massage.

Low back pain. When we changed from quadruped to a biped position, the greatest change took place between the trunk and the pelvis. This change concerned both the anatomy and the physiology. To a weakened anatomical structure was added an increased activity. The angle between the trunk and the lower extremities was increased 90 per cent. This was accomplished by stretching certain muscles and shortening others. The weight bearing alone was difficult in the new biped position, and now when we add stress and strain to this area of the body as we do so much in our industrial work, there is no wonder that low back pain is a very common occurrence that we are called upon to treat. Most injuries to the lower back involve the soft tissues only, and are not demonstrable by x-rays. I shall limit my discussion to low back injuries and exclude fractures, subluxations, arthritis, neoplasms, referred pain, etc.

What has physical therapy to offer in these back pains? If you will agree with me that a vast number of low back pains fall into a group in which no definite etiology can be established, except that of faulty body mechanics, I shall endeavor to show you how an intelligent analysis of body mechanics may lead to relief and cure in these cases. However, you have to use some discrimination in the application. In discussing this subject with a doctor who had treated many back cases among the miners in Pennsylvania, he told me how he had journeyed to Boston to learn something of exercises for low back pain. When he returned home and tried to show the coal miners a set routine of exercises, he failed completely. He decided that what was good for the Cabots and Lodges was not good for a coal miner. The correction of body mechanics has to be individual and based on careful analysis. The skeleton is maintained in correct position by the muscles. However, it depends less on muscular strength than on balance of strength between opposing muscles. If you will visualize the pelvis as a double lever with the fulcrum in the hip

joint, you will find two muscle groups opposing each other posteriorly. They are the erector spinae quadratus lumborum, pulling upward and the hamstrings, piriformis, and gluteus maximus pulling downward. Anteriorly we have the anterior abdominals, especially the rectus abdominis pulling upward, and these are opposed by the hip flexors, the rectus femoris, iliopsoas, tensor fasciae latae and sartorius which pull downward. Mr. Philip Wiles of London has shown that the action currents of these muscles vary considerably, even in the same muscle depending upon the amount of work demanded. It is easy to understand how any overwork of any of these opposing muscle groups will unbalance the leverage. The most common occurrence is probably a weakening of the abdominal muscles which throws an increased strain on the opposing back muscles. These will soon be overtaxed go into spasm and begin to ache. The whole muscle balance which keeps the pelvis in correct position is upset and the stage is set for low backache which becomes chronic unless the mechanics are carefully analyzed and corrected.

The very common sciatic syndrome which often accompanies low back pain has been described by Dr. Freiberg as being due to pressure of the piriformis muscle over the sciatic nerve.

After we have established a weakness of the abdominal muscles, shortening of the hamstrings or a muscle tear of the low back muscles as cause for unbalanced support of the pelvis our treatment consists in (1) rest for the overworked muscle (2) support for the weakened muscles followed by strengthening exercises (3) stretching of the contracted muscles by the use of heat massage and manipulation to restore flexibility (4) correction of other faulty mechanics, for example the feet which may be the primary cause for the unbalance of muscle power about the pelvis.

This approach that I have attempted to outline is useful as a preventative measure. It is the only treatment in many cases and is supplementary to the treatment of nearly all low back pains.

The future development of physical therapy lies in the hands of the traumatic surgeon and the orthopedic surgeon. Most of our traumatic patients require simple physical therapy such as heat, massage, and therapeutic exercises applied with intelligence rather than with expensive apparatus. The surgeon responsible for the case should see the patient through to the final stage of complete functional restoration. Instead of dividing the treatment into a surgical treatment

and an after treatment, they should go hand in hand.

This can be done only if the surgeon employs properly trained technicians. My criticism of the traumatic surgeon is that he does not employ the best assistants. He often uses a nurse without physical therapy training or a masseuse with inadequate training. These are often picked because of their personality rather than their professional education.

The Council on Medical Education has set down certain requirements for physical therapy technicians that will lead to a national registration, certified by the American Congress of Physical Therapy.

It is evident that in our large hospitals and big industrial centers it is advantageous both economically and professionally to have more or less extensive departments of physical therapy with a specialist at the head. The type of hospital will determine the development of this department.

CONCLUSION

1. About 75 per cent of the traumatic patients require physical therapy. Of this number 50 per cent require simple physical therapy, and 25 per cent may require some apparatus but both these groups can be handled by the surgeon and his assistant. Only in the last 25 per cent may special consultation be advisable.

2. The surgeon should be responsible for the whole treatment both the surgical and functional treatment, which should be simultaneous.

3. This can be done if the surgeon will employ properly trained technicians as assistants.

4. Departments of physical therapy in our hospitals often require a specialist in physical therapy. This department should be used as a reference department similar to x-ray and laboratory departments.

SYMPOSIUM: TREATMENT OF FRACTURES

ORGANIZATION OF REGIONAL FRACTURE GROUPS

CHARLES L. SCUDDER, M.D., F.A.C.S., Boston, Massachusetts

MORE and more am I convinced that the outstanding contribution to the treatment of fractures by American surgery in this twentieth century is the intelligent care of the injured person from the time of the accident until the resumption of pre-accident activities.

But you may say this includes every phase of the treatment of a fracture. I reply, it is intended to.

American common sense in surgery is an asset of no mean proportion. In general, in America, sound surgical judgment is more prevalent than poor surgical judgment, *but* the ignorance of professional men as to the treatment of a fracture is widespread.

Probably the incompetents and the morally obtuse of our profession can never be completely eradicated, any more than general society can be purged of those seeking something for nothing.

All of us are familiar with cases similar to the following:

CASE 1 A young adult of 24 years falls from a telephone pole while at work as a lineman. He breaks the left femoral shaft. He is taken to a nearby hospital. He is cared for by the attending surgeon. After 3 weeks, it is found that the abrasions below the knee are infected; that the thigh is curved backward and outward, and that there is shortening and no evidence of union.

CASE 2 A fracture of the leg below the knee. A plaster-of-Paris splint is applied to the whole extremity by the doctor. The nurse calls the doctor the same night, telling him the patient is in pain and that the toes on the injured side are blue. "A dose of medicine, I will see him in the morning." In the morning, the toes are black. The doctor removes the plaster splint, and an amputation at the middle of the thigh is done.

These are not isolated instances. We all know similar tragic experiences.

Such recurring instances of poor handling were the reasons for the formation of a fracture committee 16 years ago. With the increase in number and the growing complexity and seriousness of fractures, the same reasons for such a committee exist today and are more imperative than ever.

Presented in the Fracture Symposium, before the Clinical Congress of the American College of Surgeons, Chicago, October 25-29, 1937.

The surgical profession is awake to the need for improved methods of treating the injured.

There exists today a well organized movement within the surgical profession to further graduate teaching in the care of a fracture.

The 1,172 members of the fracture committee form a wide awake, active teaching group, eager to learn and ready to impart their knowledge on this important subject to the medical profession. Therefore, opportunities for graduate instruction in fractures exist in every state of these United States, and in every province in Canada.

I will present to you, today, certain of the ways in which the Regional Fracture Groups carry on in this nation wide propaganda. I will not in this brief statement tell you how each of the committees is functioning; but I have assembled a few methods which are characteristic of all the committees.

There are 66 regional committees, with a membership of 1,172. This is the largest postgraduate group attempting improvement in any surgical subject. A galaxy of teachers form this activity. Something good must result. Good has already resulted.

In general, the whole surgical profession is more alive and responsive to fractures than ever before. Individual fractures are being better treated.

The complications attending fractures are: (a) injuries to the cranial contents; (b) injuries to the spine and spinal cord; (c) injuries to the chest and its viscera; (d) injuries to the abdominal organs, with or without fracture of the pelvis; (e) nerve lesions of the extremities; (f) blood vessel damage. All these complications are being more surely recognized, and appropriate treatment is being instituted at an early date.

The disappearance of the old-time apathy of the medical profession toward fractures is not a mere coincidence. It is due in large measure to the active co-operation of the surgical profession through these regional committees.

I would not stress in this connection the rapidity of improvement in treatment, but rather the slowly moving medical mind in its apprehension of all that such co-operative action means:

better surgical results. And after all, this is our ideal better results in the treatment of fracture—making the fracture less disabling now and forever.

Every regional group in each state makes contacts with all agencies or organizations possible (1) doctors, (2) hospitals, (3) nursing associations, (4) social service organizations, (5) hospital associations, (6) medical associations and societies, (7) clubs, (8) the police, (9) fire departments, (10) safety organizations, (11) boards of health, (12) school committees, (13) trucking concerns, (14) Boy Scouts, (15) Girl Scouts, (16) American Red Cross local chapters, (17) industrial accident boards, (18) registrars of motor vehicles, (19) insurance companies, (20) the legal profession.

In what follows, I cite at random from the reported activities of the regional fracture committees in certain states. All state committees are busy some more so than others. It is important to have an active man in charge of a state committee who is informed, energetic, wide awake, and interested.

In Georgia Ambulances are all owned and manned by undertakers as is so commonly the case throughout the United States. The state association of undertakers was addressed and brought into line with the idea of the proper equipment of ambulances. The state superintendent of schools, and the superintendent of the public schools of Atlanta, both have been approached with reference to teaching first aid in fractures throughout the public schools of the state.

In Ohio The whole state is well organized being divided into districts. In the Toledo district a survey of the hospitals is being made. The president of the Ohio State Medical Society is assisting in interesting the councillors of the county societies. In the Northeastern District of Ohio clinics have been held and addresses on the treatment of fractures have been made. The local health boards and the police departments have co-operated in first aid classes. At the state medical meeting in Cleveland each day the Cleveland police drove on to the exhibition floor and demonstrated the application and use of emergency splints. The District fracture committee has asked all subcommittees to co-operate with the county medical society in arranging a meeting this winter in each of the fifteen counties and has offered to provide speakers if desired. A round table discussion was held in Cleveland of all the chairmen of the subcommittees throughout the state.

In San Francisco and the Bay Area Committees have been appointed, viz (1) an executive,

(2) an educational, (3) a hospital equipment and care, (4) a transport and ambulance committee. All members are on their toes, interested, and active. At a recent meeting, an address on interne instruction was given. It was urged that special residents be assigned to care for all fracture cases. Teaching in medical schools was discussed. An American Red Cross representative took an active part in the program.

In Minnesota The state regional committee has a definite program well under way. Just now four special subjects are being handled (1) the transport of fractures, (2) the diagnosis of fractures, (3) the hospital equipment for the treatment of fractures, (4) postgraduate education in the proper treatment of fractures.

As to transport, several members of the committee have secured passage of an ordinance in their cities requiring that proper splints be kept in the ambulances. The following is a sample ordinance.

An ordinance requiring ambulances to be equipped with first aid and splint appliances to be approved by the Board of Health and requiring an attendant with a certificate of fitness.

The City Council of the City of Crookston Do Ordain
Section 1. No person, firm or corporation shall operate or cause to be operated any ambulance public or private or any other vehicle commonly used for the transportation or conveyance of the sick or injured without having such vehicle equipped with a set of simple first aid and splint appliances approved by the Board of Health and having in attendance at all times such vehicle is in use a person who has obtained a certificate of fitness as an ambulance attendant from the Board of Health.

Section 2. Any person desiring a certificate as an ambulance attendant shall make application in writing therefor to the Board of Health. Before the issuance of any such certificate the applicant therefor must present evidence of his qualifications to fill such position and must demonstrate to the satisfaction of the Board of Health his ability to render emergency first aid and to apply properly approved splints to arm and leg fractures.

Section 3. Any person violating the provisions of this ordinance shall upon conviction thereof be punished by a fine of not to exceed One Hundred and no/100ths (\$100.00) Dollars or by imprisonment for not more than ninety (90) days.

Section 4. This ordinance shall be in force and effect from and after its passage approval publication and record.

Upon the call of ayes and nays upon the passage of the ordinance the vote stood as follows:

Aldermen voting in the affirmative Widman Emmenich, Eickhof Spence Burkley Lanster Hag a Hamerlik.

Aldermen voting in the negative None.

Upon this vote the ordinance was declared passed by the President of the Council.

Passed this 13th day of April 1937.

J. Flynn President of the Council.

Approved the 16th day of April 1937.

W. J. Kirkwood Mayor

Attest

Bergetta M. Loken City Clerk

This ordinance was published in the May, 1937, issue of *Minnesota Medicine*, page 304.

Our committee feels that in obtaining the passage of such an ordinance in the various communities permanence of the movement is established to a certain extent and also that considerable public education results. We have used the moving picture films to supplement the arguments for the ordinance in education of the city officials and also of the profession.

As to *diagnosis*, rules are posted under glass and framed in the x-ray laboratories of all hospitals for the guidance of x-ray technicians

Co-operation is maintained with the Boy Scout, Girl Scout, Red Cross, and Highway Patrol organizations to improve first aid and transport of fractures

In Vermont. At the Medical School of the University of Vermont, medical students are trained in the use of traction in the transport of fractures. A survey of the hospitals of the state has been made in so far as fractures are concerned. Motor vehicle police, now furnished with automobiles, are manned by capable young men. The State Commissioner of Motor Vehicles is equipping the cars with splints. Committee on Clinical Meetings is active in all sections of the state. The prevalence of mal-practice suits has stimulated interest in the state fracture committee.

In North Dakota The Regional Fracture Committee of North Dakota has become the Fracture Committee of the State Medical Society.

In Montana The Regional Committee is in touch with men throughout the state able and willing and ready to present papers on fractures.

In Indiana. The state is thoroughly organized with 14 operating subcommittees. A very intensive work is being done.

In Connecticut. The State Department of Education probably will sponsor this winter a state convention for all interested in first aid. The State Department of Motor Vehicles, through its commissioner, has issued a circular of information regarding fractures. It has been planned with the telephone company so that a call from any section of the state, "Send an ambulance," will result in the call being relayed to the nearest police barracks.

The present subcommittees are: membership, liaison, ambulance equipment, hospital care and equipment, education and publicity, clinical meetings, ways and means. No splints were available

so the committee had them made at low cost. National Red Cross contact is maintained.

State Printing Press is utilized so costs to committee are nothing except for paper. Committee dues are two dollars. State has a highway safety department. A Commission of State Department of Education takes care of first aid instruction.

The Aetna Life Insurance Company has sponsored an educational film, "Emergency Splinting." The state medical journal in each issue carries an article of progress in fractures. The Safety Promotion Director under Motor Vehicle Commissioner is broadcasting and sending information to newspapers interested.

In New York. Many subcommittees exist. The subcommittee on follow up is working on a standard method so as to evaluate the efficiency of different methods of treatment. Transport of spinal injuries was discussed and studied. Earlier this year there was a "Fracture Day" at the New York Academy of Medicine, with papers in the morning, luncheon and papers in the afternoon, valuable for all doctors in the neighborhood.

These are some of the ways that the state regional committees are working throughout the country, attempting to help the profession to take better care of the individual with a fracture. The organization of the state regional committees is a major development in the move to improve the treatment of fractures, and these active groups, sponsored by the American College of Surgeons, form the largest, finest, and best organized graduate teaching body in America. From the graduate educational point of view, no subject in medicine or surgery is so well covered as is the treatment of fractures.

Gentlemen, in these matters we are all concerned and interested. Whether we are members of committees or not, all of us are responsible for elevating the practice of surgery in our home communities, for bringing the art of surgery nearer and nearer to its scientific bases.

Each one of us can do something. Co-operate whenever possible with your state committee. Hold fast to the truth that the treatment of fractures and their complications demands very special training and aptitude. See to it that some one in your district is so trained: thereby the art of surgery will be furthered, and the injured man will be treated in the best manner possible.

Thus successful progress will creep from point to point, testing each step.

better surgical results. And, after all, this is our ideal better results in the treatment of fracture—making the fracture less disabling now and forever.

Every regional group in each state makes contacts with all agencies or organizations possible (1) doctors, (2) hospitals, (3) nursing associations, (4) social service organizations, (5) hospital associations, (6) medical associations and societies, (7) clubs, (8) the police, (9) fire departments, (10) safety organizations (11) boards of health (12) school committees (13) trucking concerns (14) Boy Scouts, (15) Girl Scouts, (16) American Red Cross local chapters (17) industrial accident boards, (18) registrars of motor vehicles, (19) insurance companies, (20) the legal profession.
